where v_g is the group velocity of radiation in the guide. Because p_m is typically of the order of a Bohr magneton, and the active centers are diluted, it is necessary to use *slow-wave structures* ($v_g \approx c/100$) in order to keep l to a reasonable value (a few centimeters). Suitable values of v_g are readily achieved by the resonant slowing obtained in periodic structures. Systems such as the Karp structure, comb structure, and meander line are favored, since these support waves with the magnetic field circularly polarized in a plane containing the direction of propagation and perpendicular to the plane of the periodic elements. The sense of circular polarization is reversed on crossing this plane and is opposite in any reflected wave to that in the forward wave. The nonreciprocal gyromagnetic properties of para- and

ferrimagnetic materials may then be employed to obtain forward gain and reverse attenuation with these slow waveguides.

The noise input temperature T_{in} of a traveling wave maser is given approximately by

$$T_{in} \simeq |T_m| + T_1(|Q_m|/Q_e) \quad (12)$$

where T_m is the effective negative temperature of the maser material, Q_m is the molecular Q (negative), Q_e is the similarly defined ohmic loss factor, and T_1 is the actual temperature of the waveguide (and contents). In this approximation, $|Q_m| \ll Q_e$. The bandwidth b_m of the amplifier is approximately equal to, but less than, δ .

The *Resonant circuit Maser* may be of either transmission (two-port) or reflection (one-port) type; only the reflection type is considered here, since it is superior in performance to the transmission type. Assuming that the unloaded resonant circuit (cavity) losses are negligible, the coupling to the external circuits will give rise to a Q -factor Q_e , say. The power gain G of the reflection cavity maser is then given by

$$G = (Q_e + |Q_m|)^2 / (Q_e - |Q_m|)^2 \quad (13)$$

The bandwidth b_e depends on the gain in such a way that

$$G^{1/2} b_e \simeq 2|Q_m| f_0 \text{ (for } G \gg 10, \text{ say)}$$

The noise input temperature is given by Eq. (12) above, where now

$$Q_e^{-1} = Q_e^{-1} + |Q_m|^{-1}$$

It is necessary to have some nonreciprocal device to separate the reflected amplified output from the input signal; the ferrite circulator is most commonly used. The bandwidth and gain stability of the cavity maser are inferior to that of the traveling-wave maser, but the cavity maser is more easily constructed. If three-level excitation is used, it is clear that any maser system must support both "pump" and signal frequencies.

Maser Oscillators. Equation (13) indicates that if $|Q_m|$ is small enough, G becomes infinite; i.e., oscillation occurs when the stimulated emission is small enough to overcome all losses. The width of the signal emitted by a maser oscillator is very much less than δ , so that for narrow δ an extremely pure oscillation signal results, and a molecular transition which is relatively insensitive to external influences will thus give oscillations of high stability in frequency. The ammonia maser and the atomic hydrogen maser are two examples.

Applications. Maser amplifiers are now in use wherever the requirement for a very low noise amplifier outweighs the technological problems of cooling to low temperatures. They have been used in passive and active radioastronomical work, in satellite communications ("Project Echo") and as preamplifiers for microwave spectrometry. The ammonia and the atomic hydrogen masers are being studied as frequency standards and have been used in a new accurate test of special relativity. Sources and

amplifiers in the submillimeter, micron, and optical wavelength regions are being studied and developed (see LASER).

MASS. See STATICS.

MASS AND INERTIA

One of the most fundamental and earliest known of physical phenomena is the simple fact that it takes some effort to push any object. To set some objects into motion by pushing is easier than to do the same for others. This property by virtue of which every body, however small, requires some force to push it is called "inertia."

As can easily be seen, the property of inertia is more general. Not only does it take some force to set a body in motion or to speed it up, but also to slow it down or stop it. The fact that a ball rolled on the ground soon stops is only because external forces, such as the friction on the ground, work on it to stop it. In these space days, it is not hard to believe that if a body were moving in empty space with no friction or air resistance, it would continue to move at the same speed without stopping. We also know that it takes force even to change the direction of motion of an object without any change of speed. One can feel this force while taking a car around a curve even when there is no accompanying change of speed.

All these are different manifestations of the property of inertia. This was neatly summed up by Sir Isaac Newton in the first of his laws of motion, which essentially says that a body will continue in its state of rest or of uniform motion along a straight line unless acted upon by an external force.

Given that it takes some force to change the state of motion of a body, the next question is—how much? Or, in other words, how do we

quantitatively measure the inertia of a body? Experience tells us that "heavier" or "more massive" bodies have more inertia. The exact technical measure of inertia is "mass," which is closely related to "heaviness" or "weight." The larger the mass of an object, the more the force it takes to change its motion by a given amount, i.e., to give it a certain acceleration. Newton's second law of motion tells us that the force required is just the product of the mass of the body times the acceleration given to it.

Force = mass \times acceleration

During the early stages of the development of the concept of mass, attempts were made to define it, not primarily as an index of inertia but as the "quantity of matter" in the body. Inertia was then considered to be a consequence of, and proportional to, this mass. However, it is not so easy to define precisely what one means by the "amount of matter" in an object. Clearly, one cannot use the size or volume of an object as an index of the quantity of matter or mass since a ball of wool and a ball of steel of the same size do not have the same mass. The "weight" of a body is quite often used to measure the mass, but this again is unsatisfactory since the weight of the same object can vary from place to place, even on different parts of our earth. Thus, it is best to understand mass as primarily an index of inertia, to which such properties as weight, size, etc., are closely related.

The fact that weight is such a good index of mass and has so successfully been used as a measure of mass is the key to some very important advances and speculations in physics. No discussion of inertia is complete without referring to this aspect of the story.

As we mentioned before (Newton's second law), under the action of a given force, e.g., a certain push of the hand, a body of larger mass M accelerates less than one of smaller mass m . This is evident repeatedly in daily life. However, there is one particular type of force, i.e. the gravitational force, under which all bodies react the same way. A "heavy" body and a "light" body, when dropped from a height reach the ground at the same time (except for small air viscosity corrections). The reason for this, well known to Newton himself, is that the gravitational force on a body, unlike any other type of force, is proportional to the mass or "inertia" of the body. Thus, a steel ball has large inertia and requires a large force to accelerate it by a certain amount. But the gravitational force on the steel ball is also correspondingly larger, so that under the influence of gravity alone, it would move exactly the same way a ball of cotton would. The fact that weight, which is essentially a name for the force of gravity, has been used as an index of mass is also a result of this proportionality between the two quantities.

All this, as we said, has been well known since the seventeenth century, but the deep significance of this apparent coincidence lay hidden until the time of the Viennese philosopher Ernst Mach

(1838–1916). Mach's views, developed, modified and put on a firm mathematical footing by Einstein, form one of the cornerstones of the latter's brilliant general theory of relativity. Giving a wide berth to the complexities of the general theory, we will only mention here that according to general relativists, the inertia possessed by a body is a consequence of the gravitational force acting upon it from all the stars and galaxies in the universe. When we attempt to push an object, we are accelerating it relative to all the distant massive fixed stars. This produces a resultant gravitational force, resisting the acceleration we are trying to give. This is why we have to exert a force to push a body.

Much of this is speculative and is truly meaningful only in the mathematical framework of the theory. However, interested readers may find a very lucid and simple discussion in the book "The Unity of the Universe" by D. W. Sciama.*

MASS SPECTROMETRY

Mass spectrometry is based on observations of the behavior of positive rays by Thompson and Wien. In 1919, Aston demonstrated the existence of isotopes by introducing neon gas into a mass spectrograph. Prior to 1940, mass spectrographs and spectrometers were used primarily for isotopic studies in university laboratories. Analytical spectrometers became commercially available during the early years of World War II when their use for the rapid analysis of hydrocarbon mixtures was recognized.

Mass spectrometry provides information concerning the mass-to-charge ratio and the abundance of positive ions produced from gaseous species. There are several techniques for the production and measurement of the ions, and the design of an instrument is determined by its proposed application. The mass spectrograph, using a photographic plate for ion detection was used primarily for isotopic studies but is now finding wide application for the analysis of trace constituents in solids. The mass spectrometer uses an electrical detection and recording system giving a metered output which provides a more accurate measure of the abundance of the ions than the photographic plate. The mass spectrometer is used primarily for the quantitative analysis of gases, liquids, and a limited number of solids.

The five basic components of the instrument are the sample introduction system, the ion source, the mass analyzer, the ion detector, and the recorder. A sample pressure of approximately 5×10^{-5} torr is generally required for a satisfactory analysis. An elevated temperature inlet system or other means of converting the sample

* Doubleday and Co., Garden City, N.Y.

into a gaseous state is required for less volatile species.

The most common methods of producing positive ions are electron impact, thermal ionization, spark and arc sources, and field emission. The electron impact source is the most widely used. Positive ions are produced by removing one or more electrons from the molecules. Thermal ionization produces positive ions by vaporizing material directly into the ion source from a filament coated with the sample. With a spark source, the material under investigation must be a conductor or else suitable means must be provided for initiating and maintaining a spark. Ions produced in the spark are taken directly into the mass analyzer. In the field emission source, a high potential is applied between the sample—generally deposited on the tip of a tungsten wire—and another electrode commonly in the form of a ring. Ionic species representative of the sample are removed by a high-intensity electric field.

The three most widely used types of mass spectrometers are (1) the single-focusing, magnetic deflection, (2) the double-focusing and (3) the time-of-flight (T.O.F.). These three types of instruments differ primarily in the method used for mass separation. The single-focusing analyzer with magnetic deflection is the most common design. The single-focusing analyzer achieves direction but not velocity focusing of the ions. Ions of the same mass-to-charge ratio, having slightly different velocities resulting from different kinetic energies imparted in the ionization process, will not be focused simultaneously, thus producing a broadening of the peak. The resolution of commercially available instruments of this type is generally limited to about one part in 500. That is, mass 499 can be separated from mass 500 with about a 10 per cent valley. With double-focusing instruments, an electric sector and a magnetic analyzer are placed in tandem to produce both velocity and direction focusing of the ions. Several commercial models of the double-focusing design are available having resolutions in excess of one part in 10000 with an electron impact source, and greater than one part in 3000 with a spark source. The double-focusing geometry is necessary with spark source operation because of the wide energy spread of ions produced in the spark. With both single- and double-focusing, the resolution varies directly with the radius of the analyzer tube and inversely with the width of the slits located in the ion source and ion collector regions. Sensitivity, the abundance of the ions collected per unit sample charge, varies inversely with slit width, and a compromise must be made between resolution and sensitivity. In the T.O.F. design, all ions produced in the source are accelerated through a given electric field and achieve velocities inversely proportional to their masses. Mass separation results from the different times required for various mass ions to traverse the distance to the collector through a linear drift tube. Resolution on the order of 1 part in 300 to 500 can be obtained with this type of mass

analyzer. The major advantage of the T.O.F. instrument is its rapid production and recording of spectra. Over 10000 mass spectra can be produced each second extending through a mass range from 1 to 5000. Other types of mass resolving systems include cycloidal, omegatron, and quadrupole designs.

The two types of ion detection and recording systems are the photographic plate and the electrical detector. The photographic method is commonly used with double-focusing instruments such as the Mattauch-Herzog design which focuses all ions simultaneously in one plane. The photographic plate records a complete spectrum (mass range $\sim 36:1$) in a time interval of a few seconds to 10 minutes. However, the response of the plate to the ion intensity is non-linear and quantitative results are more difficult to obtain than by electrical detection. Electrical detection systems use an ion collector, amplifier, and recorder.

Positive and negative ions and neutral species are produced by the electron bombardment of molecules. The mass spectrum of a compound is a record of the positive ions collected. Positive ions are produced by the removal of one or more electrons from the molecule and by the rupture of one or more bonds, fragmenting the molecule. While the majority of the positive ions are singly charged, doubly and triply charged ions are observed in many instances. Certain mass ions produced from organic molecules must be attributed to the rearrangement of hydrogen atoms during the ionization and fragmentation processes. Metastable ions, formed when ions decompose while traversing the path to the collector, are also frequently observed. Metastable ions generally appear at non-integral mass units.

In the electron impact source, the electron energy is usually adjusted to 50 to 70 eV which is considerably above the appearance potential for molecular and fragment ions. For simplification of a complex spectrum, the bombarding energy can be reduced to provide sufficient energy to ionize the molecule but not enough to rupture bonds, thus achieving a spectrum consisting only of molecular ions. Mass ions appearing in the normal mass spectrum correspond to the various atoms and combinations of atoms in the original molecule. The pattern of mass-ion intensities observed is independent of pressure. Differences in the patterns obtained for various compounds can be used as the basis for the analysis of complex mixtures. Quantitative analysis is based on the ion current varying linearly with the partial pressure of the gas.

Some of the common uses for mass spectrometry include analysis of petroleum products, determination of the structure of organic molecules, determination of trace impurities in gases, residual vacuum studies and leak detection in high-vacuum systems, geological age determinations, tracer techniques with stable isotopes, determination of unstable ionic species in flames, identification of compounds separated by gas-chromatography, trace element analysis in metals

and other solids, microprobe studies of surfaces and studies of surface composition of various materials.

MATHEMATICAL BIOPHYSICS

The term was coined in 1934 by N. Rashevsky to denote a science which applies methods of mathematical physics to biology, just as "biophysics" applies methods of general and experimental physics to biology. Lately a more general term, *mathematical biology*, has been introduced. Mathematical biology stands in the same relation to experimental biology as mathematical physics to experimental physics. This means that mathematical biology develops mathematical theories of various biological phenomena, with the aim of better understanding their nature and of suggesting new avenues for experimental approach. Contrary to mathematical biophysics, however, mathematical biology does not necessarily introduce definite physical models. Some work on mathematical biology may be considered as a construction of purely formal mathematical models of biological phenomena. On the other hand, mathematical biophysics does specifically deal with physical models. Thus mathematical biology includes mathematical biophysics. It is not advantageous to attach specific labels to any particular scientific endeavor, especially in these days of increasing interdisciplinary research. Attaching such labels in science may be just as unwise as attaching definite labels to social and political situations. At best, it may be meaningless. Therefore, in a particular instance it may be difficult, if not impossible, to decide whether a given research belongs to mathematical biophysics or to mathematical biology.

The classical works of Alfred J. Lotka and of Vito Volterra, as well as the similar work by V. A. Kostitzin, on the interaction of species, as well as the wealth of mathematical work on genetics (Sewall Wright, J. B. S. Haldane) should be classed as mathematical biology. In this work no specific physical mechanisms are discussed. It is more formal or phenomenological. On the other

hand, the mathematical work on the models of cardiovascular system, which dates back to Leonard Euler in 1775, and which formed the subject of numerous papers by O. Frank between 1899 and 1928 (*Zeitschrift f. Biologie*), as well as the more recent work of S. Roston and Freeman Cope, J. Womersley, and Allen King on the elasticity of blood vessels, must definitely be considered as mathematical biophysics, even though much of that work was done before the term was coined. Similarly, the work of Braune and Fisher, at the turn of the century, on the dynamics of human locomotion is mathematical biophysics.

Mathematical biology is now frequently referred to as *biomathematics*. The latter term has the advantage of being shorter, but it suffers from a serious etymological shortcoming. One never uses the word *physicomathematics* or *physical mathematics*, instead of mathematical physics. The noun which denotes the principal field of study is *physics*. The word *mathematical* is used, as an adjective, to denote the type of tools used. Mathematics remains the same, whether it is applied in physics, in engineering or in biology. But mathematical physics and mathematical biology are different in the approaches to their problems from experimental physics or experimental biology.

From the point of view of the definition of mathematical biophysics given here, it is not quite as young a science as it appears to be. In fact, biological literature has been for quite some time sporadically sprinkled with studies which are essentially mathematical biophysics.

After coining this word in 1934, N. Rashevsky and his associates at the University of Chicago began a concerted effort of developing mathematical biophysics in a systematic way. For a while this concentrated effort was largely limited to the University of Chicago. Gradually, however, partly due to the migrations of individuals of the group, partly quite independently, work in mathematical biophysics began to spread very widely. The work of the Chicago group became gradually more general, and the many aspects of it are now better described by the more general term *mathematical biology*. There is no entirely comprehensive treatise that encompasses *all* the work done in mathematical biophysics. The references at the end of this article give a limited list of books and journals, some of which deal both with mathematical biophysics as well as more generally with the broader aspects of mathematical biology. The interested reader will find in these references a lead for further study.

In 1939 a special journal was founded by N. Rashevsky, *The Bulletin of Mathematical Biophysics*. It is now in its twenty-seventh year of existence. The *Journal of Theoretical Biology*, founded in 1961 by J. F. Danielli, is devoted to essentially the same subject. A number of important papers on mathematical biophysics has been published in the relatively new *Biophysical Journal* which is devoted to both experimental and theoretical work in biophysics. A great deal of important work in mathematical biophysics is

scattered throughout numerous classical journals in physiology and general biology. Hundreds of papers have been published in the *Bulletin of Mathematical Biophysics* alone. The aim of this article is therefore not to give a detailed mathematical discussion of any particular problems of mathematical biophysics, but rather to mention only *some* of the important work. The work that is not mentioned is omitted only because of lack of space, and not because it is considered as less important.

We have already mentioned the work on cardiovascular phenomena and on the dynamics of human locomotion. The work of Rashevsky began with an unsuccessful attempt at developing a theory of cell division on the basis of so-called diffusion drag forces. Those forces appear in any diffusion field and are due to the interaction between the molecules of the diffusing solute and those of the solvent. Since diffusion phenomena are known to be widespread in cells, the idea was investigated mathematically, as to whether the diffusion drag forces may not be the cause of cell division. Mathematically the problem divided into three parts: the calculation of diffusion fields, the calculation of diffusion drag forces, and the calculation of their possible mechanical effects. It was possible to show that under certain conditions those forces will produce a fission of a cell as a whole. Not only did the theory lead to correct order of magnitude for the average size of cells, but also to a correct quantitative representation of the over-all phenomena of original elongation and eventual construction of such cells as demembrated *Achacia* eggs. Yet the theory failed completely in accounting for the all-important phenomena in the mitotic apparatus. The theory was developed at the time when little was known of the fine phenomena of replication of the smallest parts of the cell. It was based on the physics of "matter in bulk," whereas it is now clear that the whole problem must be attacked on a molecular level.

Nevertheless a number of side problems turned out to be of use. Thus the theoretical study of the limitation of cellular biochemical reactions by the diffusion processes led to a theory of the dependence of the rate of cell respiration on the amount of available oxygen. The theory was found to be in agreement with available data (H. D. Landahl).

An elaboration of the theory of diffusion drag forces led to a theory of self-regulating cell polarity and to a representation of some embryological phenomena.

Another example of the work of the Chicago group is H. D. Landahl's study of the retention of particulate material contained in the air inhaled through the respiratory tracts. This retention is due to a number of physical factors, such as impaction against nasal hairs, impaction against the mucus covered walls of the passages, Brownian movement and sedimentation. The results of this theoretical work are of great practical importance.

One of the most important fields of mathematical biophysics is the theory of biological

membrane potentials, and the theory of transport across biological membranes. The classical work of J. F. Danielli on the structure of membranes must be mentioned here. Theoretical problems of transport across the membrane have been studied by H. H. Ussing, J. Frank and J. E. Meyer, C. Patlak, D. E. Goldman, and many others. The problems deal largely with the phenomenon of the transport of sodium and potassium ions from the side of the membrane where the concentration is lower, to the side where it is higher. Torsten Teorell has studied mathematically transport phenomena in membranes which involve not only the movements of ions but also the movement of water. He has shown, both mathematically and experimentally that periodic fluctuations of the membrane potential do arise under certain conditions. Those potential changes look remarkably similar to potential changes in repetitive nervous discharges, and thus give a possible clue for the understanding of phenomena of nervous excitation.

Kenneth Cole and his associates have contributed important experimental studies of the electrical properties of biological membranes, especially of their impedance. Their work is largely studded with interesting mathematical interpretations, which must be considered as falling into the domain of mathematical biophysics. Interesting physical models, which offer an explanation of the formal equivalence of some biological membranes with what is known as "equivalent electric circuits," have been recently studied by A. Mauro.

Somewhat in a class by itself stands the very important work of A. L. Hodgkin and A. F. Huxley on the mathematical description of nerve excitation. From a series of experiments, they come to the conclusion that the appearance of the action potential is due to the movement of sodium ions inward, into the nerve fiber, which makes the outside negative. The decrease of the action potential is interpreted as due to an outward movement of potassium ions. Empirical relations governing these movements are determined from experiments. The validity of the arguments which lead to those empirical relations is not yet generally recognized. Hodgkin and Huxley then show that from those empirical relations, obtained physiologically under somewhat artificial conditions of a "voltage clamp" which maintains a constant voltage in spite of redistribution of ions, the general shapes of the action potential curves can be calculated. Strictly speaking, the work of Hodgkin and Huxley does not represent a theory in the usual sense of the word. The authors themselves feel that they cannot go back to "first principles." Thus their work, in a sense, represents an empirical mathematical description of some important phenomena by means of a series of very complicated empirical equations. This, in spirit, is rather different from the deductive approach of a mathematical biophysicist. Yet some definite physical pictures are assumed, and their work therefore may be considered as falling at least partly into the domain of mathematical biophysics.

A great deal of mathematical work has been done in biochemistry. It covers, for example, such phenomena as biochemical reaction rates, enzyme activity, etc. To the extent that chemistry itself has now, through quantum mechanics, become a branch of physics, the above-mentioned studies do fall also into the domain of mathematical biophysics. This is enhanced by the fact mentioned in connection with Rashevsky's studies, that purely physical phenomena, such as diffusion, do impose limitations upon, and thus affect, the purely biochemical processes (J. Z. Heaton). This interaction of biophysics and biochemistry is brought to light particularly in the theory of distribution of different metabolites between the different "compartments" of an organism, between which there may be transport of material either by diffusion, convection, or some other mechanisms. This theoretical work is of particular importance for biological studies of movements of metabolites by means of radioactive tracers. In this connection the important work of C. W. Sheppard, J. S. Stevenson, A. Rescigno and G. Segré, and others should be mentioned.

A special application of this type of study has been made to the effects of drugs which are carried to various places in an organism. Here we must mention the beautiful recent work of R. Bellman, R. Kalaba and J. A. Jacquez. More elementary studies of this type date back some 30 years, to W. Gehlen and E. Beccari.

A great deal of mathematical work has been done on the central nervous system. Most of it, however, is of the broader nature of mathematical biology, rather than mathematical biophysics. Nevertheless, the work of W. Rall on the transmission at synapses must be considered as belonging to mathematical biophysics.

The mathematical theory of the regulation of the functions of the lung (J. Defares) should also be mentioned, as well as the work of L. Danziger and G. Elmergreen, and the quite recent work of N. Rashevsky, on oscillatory phenomena in the endocrine system. The size of this article, however, does not permit us to give justice to all the important work that has been done in mathematical biophysics. Instead, we have merely tried to give a general idea of what kind of problems have been studied. The reader will find much more in the references.

MATHEMATICAL PHYSICS

The term "mathematical physics" is almost synonymous with "THEORETICAL PHYSICS," but their difference is significant. It is like the difference between the descriptions of the electromagnetic field by Maxwell and by Faraday respectively. The theoretical (nonmathematical) description draws on analogies between elements of the field and familiar mechanical models—stretched strings, compressed fluids, vortex motion, etc.; the mathematical description made use of the abstract analytical properties of the elements of the field to set up a purely symbolic description without mechanical models. Classical theoretical physics was largely mathematical in content, but was nevertheless based on mechanical models in the spirit of Faraday's theory of the electromagnetic field. The atom and interactions between atoms were regarded as the "real," "external" objects in terms of which all physical phenomena could be explained. The mathematical formalism was merely a handy tool or language in terms of which to set up the explanation. The atoms themselves were not explained, but regarded as the fundamental "building blocks" of the physical world.

Einstein's theory of RELATIVITY is a magnificent historical example of mathematical physics we may cite to contrast with the classical atomic theory. Here mathematical abstractions, Minkowski space 4-vectors, Riemannian tensors, etc. were invented or adopted from the stock-in-trade of pure mathematicians, with analytical properties that were seen to match those of the data of experimental physics—velocities, forces, field variables, etc. Then the logical (i.e., mathematical) consequences of relations among these abstractions predicted new and unexpected relations among either already known or as yet undiscovered data of experimental physics. The construction of a self-consistent mathematical

description of all physical phenomena, without the use of hypothetical building blocks of any kind, is the aim of mathematical physics as distinct from theoretical physics.

The activities of mathematical physicists have resulted in the invention of new mathematical abstractions some of which were at first rejected by pure mathematicians as illogical, only later to be granted a respectable status in the vocabulary of pure mathematics. Examples include Oliver Heaviside's operational calculus, J. Willard Gibbs' vector analysis, and P. A. M. Dirac's delta-function techniques. On the other hand, many branches of pure mathematics which initially had been regarded as so abstract as to be entirely "useless," have been found by mathematical physicists to serve as remarkably useful tools in describing physical phenomena. Examples include non-Euclidean geometry in the problems of COSMOLOGY; function space in modern QUANTUM MECHANICS; spinor analysis, or the theory of binary forms, in quantum FIELD THEORY. Again collaboration between mathematical physicists and mathematicians has in recent years resulted in the construction of new disciplines of great value, examples being group theory, operations analysis, the theory of random functions, information theory, and CYBERNETICS. The names of many contemporary scientists are involved here, including Eugene P. Wigner, John von Neumann, C. E. Shannon, Norbert Wiener and many others.

On closer examination it becomes difficult to distinguish clearly between mathematical physics and applied mathematics; very frequently the same individual may be responsible for discoveries in both areas. Classical examples of this may be cited: Isaac Newton, Laplace, Carl Friedrich Gauss, Henri Poincaré, David Hilbert, Ernst Mach, A. N. Whitehead. Evidently our attempt to define mathematical physics is degenerating into a simple catalog of items with only a vague hint of general characteristics common to all particulars. Physics has sometimes been defined as what physicists do, and one is expected to recognize the physicist without need for further definition than his own affirmation. Mathematical physics may then be defined as what physicists do with mathematics, or what mathematicians do with physics, or some superposition of the two. As the history of mathematical physics unfolds it becomes apparent that activity tends to cluster in a few fruitful directions at any one time. Current interests can be judged from the contents of the leading journals devoted to the subject; among these the reader should consult the *Journal of Mathematical Physics*, and the *Physical Review*, published by the American Institute of Physics; *The Proceedings of the Cambridge Philosophical Society*; *Comptes Rendus* (French Academy of Sciences), *Progress of Theoretical Physics* (Japan), *Nuovo Cimento* (Italy), *Indian Journal of Theoretical Physics*, *Zhurnal Eksperimental'noy i Teoreticheskoy Fiziki* (USSR) (in English Translation "JETP") and other translations published by the American Institute of Physics. Probably the most popular

fields in recent years have been in the wide application to solid-state physics and statistical mechanics of quantum field theoretical techniques introduced initially to deal with the phenomena of high energy physics—nuclear interactions, creation and destruction of particles, etc.

A philosophy of mathematical physics has gradually evolved with all this creative activity. Among the best sources for a study of this the reader is referred to some semi-popular expositions:

Kenneth Ford, "The World of Elementary Particles," Blaisdell Publishing Co., 1963.

James R. Newman, "The World of Mathematics," Simon and Schuster, 1956 (especially Vol. II).

More technical references of a general scope include the classic work in Germany by R. Courant and D. Hilbert, recently translated into English:

Courant and Hilbert, "Methods of Mathematical Physics," Interscience, 1953 and 1962.

Many College courses of theoretical physics are based on the series of volumes by Arnold Sommerfeld, published by Academic Press. A more advanced reference is the two volume set "Methods of Theoretical Physics," by Morse and Feshbach. A less ambitious volume serves as an advanced undergraduate text: "Introduction to Mathematical Physics" by W. Band. An excellent reference work is "The Mathematics of Physics and Chemistry" by Margenau and Murphy in two volumes. Many other references will be found in these two texts.

WILLIAM BAND

MATRICES

Matrix notation and operations are introduced into theoretical physics so that algebraic equations and expressions in terms of rectangular arrays of numbers can be systematically handled.

An $n \times m$ matrix $A = (a_{ij})$ possesses n columns and m rows, having in double suffix notation the form

$$A = \begin{pmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ \cdot & \cdot & \cdots & \cdot \\ a_{m1} & a_{m2} & \cdots & a_{mn} \end{pmatrix}$$

The general element a_{ij} may be a complex number. If all elements are zero, A is the null matrix O or 0 . When $n = 1$, the matrix is a column vector v . If $m = n$, A is square of order n ; if all elements not on the leading diagonal $a_{11}, a_{22}, \dots, a_{nn}$ are zero, the matrix is a diagonal matrix D , while D is the unit matrix I if $a_{11} = a_{22} = \cdots = a_{nn} = 1$.

The sum or difference of two $n \times m$ matrices A and B is an $n \times m$ matrix $C = A \pm B$, where $c_{ij} = a_{ij} \pm b_{ij}$. The elements of αA are αa_{ij} .

The transpose of A is denoted by A' ; this is an $m \times n$ matrix whose i th row and j th column are identical respectively with the j th column and i th row of A . Hence v' is a row matrix with m elements. For convenience, the column v is often printed as a row with braces, $\{v_1 v_2 \cdots v_m\}$.

The product $C = AB$ is only defined when the number of columns of A equals the number of rows of B ; A and B are then conformable for multiplication. If A is $n \times m$ and B is $p \times n$, then C is $p \times m$, with

$$c_{ij} = \sum_{k=1}^n a_{ik}b_{kj}$$

Generally, multiplication is not commutative, but it is always associative. The transpose of a product is given by $(ABC)' = C'B'A'$.

If A is square, then A is symmetric if $A = A'$, while if $A = -A'$ it is skew-symmetric. A quadratic form S_A in the n variables contained in the column $x = \{x_1, x_2, \dots, x_n\}$ may be written as $S_A = x'Ax$, where A is symmetric.

Let $\det A \equiv |A|$ denote the determinant of the square matrix A . If $\det A \neq 0$, A is non-singular. Then the definition of matrix multiplication ensures that

$$\det(AB) = \det A \det B$$

where A and B are square matrices of the same order.

The cofactor of a_{ij} in the square matrix A equals $(-1)^{i+j}$ times the determinant formed by crossing out the i th row and j th column in A . The adjoint of A , denoted by $\text{adj } A$, is the transpose of the matrix formed when each element of A is replaced by its cofactor. We have

$$A \text{ adj } A = (\text{adj } A)A = (\det A)I$$

and $\det(\text{adj } A) = |A|^{n-1}$. The unique reciprocal or inverse of a non-singular matrix A is given by

$$A^{-1} = (\text{adj } A)/\det A$$

This has the property that $AA^{-1} = A^{-1}A = I$. It follows that

$$(AB)^{-1} = B^{-1}A^{-1}$$

Linear equations relating n variables x_i to n variables y_i may be expressed as $x = Ay$; if $\det A \neq 0$, the unique solution for the y_i in terms of the x_i is $y = A^{-1}x$.

The rank of an $n \times m$ matrix A is the order of the largest non-vanishing minor within A ; of the m linear expressions Ax , the rank gives the number that are linearly independent. The m linear equations in n unknowns $Ax = d$, where d is a column with m elements, are consistent if the rank of A equals the rank of the augmented matrix, $(A \ d)$.

If the m linear equations $Ax = d$ are inconsistent, the "best" solution in the least squares sense for x_1, x_2, \dots, x_n is given by the normal equations

$$A'Ax = A'd$$

An $n \times n$ matrix A is orthogonal if $A'A = I$, that is, if $A^{-1} = A'$. Clearly, $|A| = \pm 1$. If c_i denotes the i th column of A , then $c_i'c_i = 1$ and $c_i'c_j = 0$ if $i \neq j$; similar results hold for the rows. The transformation $x_1 = Ax$ represents a rotation of rectangular Cartesian axes in three dimensions;

$|A| = +1$ if the right-handed character is preserved. The element λ_{ij} equals the cosine of the angle between the $(x_1)_i$ and x_j axes. If N is skew-symmetric, then $(I + N)^{-1}(I - N)$ is orthogonal.

Matrices with complex elements are manipulated according to the same rules. A square matrix H is Hermitian if $H' = H$, and skew-Hermitian if $H' = -H$, a star denoting the complex conjugate. A unitary matrix U satisfies $U' = U^{-1}$, the columns (and rows) enjoying the properties $c_i'c_j = 1$ if $i = j$ and 0 if $i \neq j$.

First- and second-order tensors, arising in many physical problems, may be expressed in matrix notation. If $x_1 = Ax$ denotes a rotation of rectangular Cartesian axes, A being orthogonal, then $f_1 = Af$ and $F_1 = AF A'$ define Cartesian tensors of orders 1 and 2 respectively. Evidently, if u and v are vectors or tensors of order 1, then $u'v$ is an invariant, Fu is a tensor of order 1 and uv' is a tensor of order 2. For example, the vector product $u \times v$ may be written as Uv , where

$$U = \begin{pmatrix} 0 & u_3 & u_2 \\ u_3 & 0 & -u_1 \\ -u_2 & u_1 & 0 \end{pmatrix}$$

U is a tensor of order 2 if u is a vector; U' is the dual of u .

But if $x_1 = Ax$, where A is not orthogonal, $f_1 = Af$ defines a contravariant vector, but $g_1 = A'g$ defines a covariant vector. The product $g'f$ is now an invariant.

If A is square of order n , then the n homogeneous equations $Ax = \lambda x$ require $\det(A - \lambda I) = 0$ for non-trivial solutions. This characteristic equation possesses n characteristic or latent roots; if they are all distinct, n corresponding characteristic or latent vectors exist. The vector k_i corresponding to the root λ_i may consist of the n cofactors of any row of $A - \lambda_i I$; at least one non-trivial row exists.

The following properties are important. If A is real and symmetric, and if λ_i and λ_j are distinct, then $k_i'k_j = 0$; these two vectors are orthogonal. Again, if A is real and symmetric, the n values of λ are real, but if A is real and skew-symmetric, these n values are pure imaginary. For a real orthogonal matrix A , $|\lambda_i| = 1$ for all i . The characteristic roots of A^{-1} are $1/\lambda_i$, k_i still being the corresponding vectors. If $|\lambda_1|$ is the largest of the moduli of the n roots, then as $r \rightarrow \infty$, $A^r x \rightarrow k_1$, where x is an arbitrary column.

If A is symmetric, n mutually orthogonal characteristic vectors may be found even if the roots are not all distinct. If each vector k_i is normalized, i.e., divided by $\sqrt{(k_i'k_i)}$, then the matrix

$$A = (k_1 \ k_2 \ \dots \ k_n)$$

is orthogonal, and the product $A'A$ equals D , the diagonal matrix consisting of the n roots arranged down its leading diagonal in order. The matrix A is said to be diagonalized.

More generally, if A is a general square matrix of order n , then n independent vectors k_i may be

found corresponding to the n roots if the latter are distinct. Then

$$\mathbf{T} = (\mathbf{k}_1 \ \mathbf{k}_2 \ \dots \ \mathbf{k}_n)$$

transforms \mathbf{A} into diagonal form thus: $\mathbf{T}^{-1}\mathbf{A}\mathbf{T} = \mathbf{D}$. If the n roots are not all distinct, this reduction may or may not be possible; it is always possible if \mathbf{A} is symmetric. Note $\mathbf{A}^n = \mathbf{T}\mathbf{D}^n\mathbf{T}^{-1}$.

Similar remarks apply to Hermitian matrices \mathbf{H} . If $\mathbf{H}\mathbf{k} = \lambda\mathbf{k}$, all the n values of λ are real, and n vectors can always be found such that $\mathbf{k}^*\mathbf{k}_j = \delta_{ij}$. The unitary matrix $\mathbf{U} = (\mathbf{k}_1\mathbf{k}_2 \dots \mathbf{k}_n)$ transforms \mathbf{H} into diagonal form.

Two quadratic forms $S_A = \mathbf{x}'\mathbf{A}\mathbf{x}$, $S_B = \mathbf{x}'\mathbf{B}\mathbf{x}$, where \mathbf{A} and \mathbf{B} are symmetric and of the same order, may be reduced simultaneously to sums of squares. The equations $\mathbf{A}\mathbf{k} = \lambda\mathbf{B}\mathbf{k}$ demand $\det(\mathbf{A} - \lambda\mathbf{B}) = 0$; this possesses n roots λ_i and n corresponding vectors \mathbf{k}_i . If

$$\mathbf{T} = (\mathbf{k}_1 \ \mathbf{k}_2 \ \dots \ \mathbf{k}_n)$$

then $\mathbf{T}'\mathbf{A}\mathbf{T}$ and $\mathbf{T}'\mathbf{B}\mathbf{T}$ are both diagonal. The transformation $\mathbf{x} = \mathbf{T}\mathbf{y}$ yields the two sums of squares $S_A = \mathbf{y}'(\mathbf{T}'\mathbf{A}\mathbf{T})\mathbf{y}$ and $S_B = \mathbf{y}'(\mathbf{T}'\mathbf{B}\mathbf{T})\mathbf{y}$. In particular, if S_A is positive definite, $\mathbf{T}'\mathbf{A}\mathbf{T}$ will equal \mathbf{I} if new columns $\bar{\mathbf{k}}_i$ are used in \mathbf{T} , where $\bar{\mathbf{k}}_i = \mathbf{k}_i/\sqrt{(\mathbf{k}_i'\mathbf{A}\mathbf{k}_i)}$.

Necessary and sufficient conditions for the real quadratic form S_A to be positive definite for all real $\mathbf{x} \neq 0$ are that the n determinants

$$\begin{vmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{vmatrix}, \begin{vmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{vmatrix}, \dots, \det \mathbf{A}$$

should be positive. This ensures that the n characteristic roots of \mathbf{A} are all positive.

Finally, matrices may often usefully be partitioned employing matrices within matrices. Multiplication may still be performed provided each individual matrix product is permissible. For example,

$$\begin{pmatrix} \mathbf{a} & \mathbf{b}' \\ \mathbf{c} & \mathbf{D} \end{pmatrix} \begin{pmatrix} \mathbf{e} & \mathbf{f}' \\ \mathbf{g} & \mathbf{H} \end{pmatrix} = \begin{pmatrix} \mathbf{ae} + \mathbf{b}'\mathbf{g} & \mathbf{af}' + \mathbf{b}'\mathbf{H} \\ \mathbf{ce} + \mathbf{D}\mathbf{g} & \mathbf{cf}' + \mathbf{D}\mathbf{H} \end{pmatrix}$$

where \mathbf{a} , \mathbf{e} are scalars, \mathbf{b} , \mathbf{c} , \mathbf{f} , \mathbf{g} are 1×3 columns and \mathbf{D} , \mathbf{H} are 3×3 .

Applications. Differential Equations. If $d\mathbf{x}/dt + \mathbf{A}\mathbf{x} = \mathbf{f}$, \mathbf{A} being constant and $\mathbf{f} = \{f_1(t), f_2(t), \dots, f_n(t)\}$, then if \mathbf{T} diagonalizes \mathbf{A} , $\mathbf{x} = \mathbf{T}\mathbf{y}$ yields n non-simultaneous equations $dy_i/dt + \lambda_i y_i = \mathbf{T}^{-1}\mathbf{f}$. If $y_0(t)$ is a particular integral,

$$\mathbf{x}(t) = \mathbf{T} \begin{pmatrix} e^{-\lambda_1 t} & \dots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \dots & e^{-\lambda_n t} \end{pmatrix} \times [\mathbf{T}^{-1}\mathbf{x}(0) - \mathbf{y}_0(0)] + \mathbf{T}\mathbf{y}_0(t)$$

Geometry. In three-dimensional Cartesian co-ordinates,

$$\mathbf{a}'\mathbf{x} + d = 0$$

represents a plane, the perpendicular distance from \mathbf{x}_1 being

$$(\mathbf{a}'\mathbf{x}_1 + d)/\sqrt{(\mathbf{a}'\mathbf{a})}$$

The equation $\mathbf{x}'\mathbf{A}\mathbf{x} = d$ represents a central quadric. If \mathbf{A} diagonalizes \mathbf{A} , the rotation $\mathbf{x} = \mathbf{A}\mathbf{x}_1$ yields $\mathbf{x}_1'\mathbf{D}\mathbf{x}_1 = d$. The vectors \mathbf{k}_1 , \mathbf{k}_2 , \mathbf{k}_3 specify the three principal axes, of semi-lengths $\sqrt{(d/\lambda_i)}$ when $d/\lambda_i > 0$.

Dynamics. The rotational equations of motion of a rigid body with respect to moving axes fixed in the body and with the origin fixed in space or at centre of mass are

$$\mathbf{g} = \mathbf{J}\dot{\boldsymbol{\omega}} + \boldsymbol{\Omega}\mathbf{J}\boldsymbol{\omega}$$

where \mathbf{g} = couple, $\boldsymbol{\omega}$ = angular velocity, $\boldsymbol{\Omega}' = \text{dual } \boldsymbol{\omega}$, \mathbf{J} denotes the inertia tensor $= \sum m\mathbf{X}\mathbf{X}$, where $\mathbf{X}' = \text{dual } \mathbf{x}$. Explicitly,

$$\mathbf{J} = \begin{pmatrix} A & H & G \\ H & B & F \\ G & F & C \end{pmatrix}$$

The rotational kinetic energy is $\frac{1}{2}\boldsymbol{\omega}'\mathbf{J}\boldsymbol{\omega}$. When principal axes of inertia are chosen, \mathbf{J} is diagonal, yielding Euler's equations.

Small oscillations about a position of equilibrium are investigated by considering the second order approximations

$$K.E. = \dot{\mathbf{q}}'\mathbf{A}\dot{\mathbf{q}}, \quad P.E. = \mathbf{q}'\mathbf{B}\mathbf{q}$$

\mathbf{q} containing n generalized coordinates measured from their equilibrium values. \mathbf{A} and \mathbf{B} are constant symmetric matrices. If the n roots of $\det(\mathbf{A} + \lambda\mathbf{B}) = 0$ are considered, and if $\mathbf{q} = \mathbf{T}\mathbf{x}$, where $\mathbf{T} = (\mathbf{k}_1\mathbf{k}_2 \dots \mathbf{k}_n)$ reduces \mathbf{A} to the unit matrix \mathbf{I} , the equations of motion are

$$\ddot{\mathbf{x}}_i + (1/\lambda_i)\mathbf{x}_i = 0$$

The elements of \mathbf{x} are the *normal coordinates*; each individual solution x_i in terms of the q 's is a *normal mode* of period $2\pi\sqrt{\lambda_i}$.

Electromagnetic Theory. Maxwell's 3×3 stress tensor in matrix notation is

$$\mathbf{T} = \frac{1}{2}[2\epsilon\mathbf{e}\mathbf{e}' + 2\mu\mathbf{h}\mathbf{h}' - \epsilon(\mathbf{e}'\mathbf{e})\mathbf{I} - \mu(\mathbf{h}'\mathbf{h})\mathbf{I}]$$

in mks rationalized units. The field exerts a force across an area element $\mathbf{n} \delta S$ equal to $\mathbf{T}\mathbf{n} \delta S$.

When electromagnetic waves are propagated in an ionized medium the equation

$$\text{curl curl } \mathbf{e} = k^2(\mathbf{I} - \mathbf{M})\mathbf{e}$$

arises, where

$$\mathbf{M} = X(Y^2\mathbf{nn}' + iY\mathbf{N} - \mathbf{I})/(Y^2 - 1)$$

in the usual notation with collisions neglected; here, \mathbf{n} = unit vector directed along the external magnetic field, $\mathbf{N}' = \text{dual } \mathbf{n}$. These equations may be rearranged in terms of the matrix

$$\mathbf{f} = \{E_x, E_y, Z_0H_x, Z_0H_y\}$$

giving $d\mathbf{f}/dz = -ik\mathbf{T}\mathbf{f}$, where \mathbf{T} is a 4×4 matrix. If the characteristic roots $\lambda_i(z)$ of \mathbf{T} are found, and if \mathbf{R} diagonalizes \mathbf{T} , then the transformation $\mathbf{f} = \mathbf{R}\mathbf{g}$ yields

$$\frac{d\mathbf{g}}{dz} = -ik\mathbf{D}\mathbf{g} \quad \mathbf{R}^{-1} \frac{d\mathbf{B}}{dz} \mathbf{g}$$

The solutions of the approximate equations $d\mathbf{g}/dz = -ikD\mathbf{g}$ are related to the characteristic waves propagated in the medium.

Special Relativity. If $\mathbf{x} = \{ict, x, y, z\}$ refers to an inertial frame S , and if a second parallel frame S_1 has uniform relative velocity U along Ox , the Lorentz transformation is $\mathbf{x}_1 = \Lambda_1 \mathbf{x}$, where

$$\Lambda_U = \begin{pmatrix} \beta & iU\beta/c & 0 & 0 \\ iU\beta/c & \beta & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

Λ is orthogonal, and $\beta = 1/\sqrt{1 - U^2/c^2}$. We have $\Lambda_1 \Lambda_{1'} = \Lambda_{11'}$, where

$$W = (U + V)/(1 + UV/c^2).$$

For the general velocity \mathbf{v} relating parallel frames,

$$\Lambda = \begin{pmatrix} \beta & i\beta\mathbf{v}/c \\ i\beta\mathbf{v}/c & 1 + (\beta - 1)\mathbf{v}\mathbf{v}'/c^2 \end{pmatrix}$$

The operator $\square = \{\partial/\partial ict, \partial/\partial x, \partial/\partial y, \partial/\partial z\}$ is a four vector satisfying $\square_1 = \Lambda \square$; so are the four-current \mathbf{i} and the four-potential \mathbf{b} ,

$$\mathbf{i} = \begin{pmatrix} ic\rho \\ \mathbf{j} \end{pmatrix}, \quad \mathbf{b} = \begin{pmatrix} i\phi/c \\ \mathbf{a} \end{pmatrix}$$

where \mathbf{a} is the vector potential. They satisfy $\square \cdot \mathbf{i} = 0$ (conservation of charge), $\square \cdot \mathbf{b} = 0$ (the Lorentz relation). Maxwell's equations in mks units in free space take the form

$$\square \cdot \mathbf{F} = i/\epsilon_0 c^2$$

$$\square \cdot \mathbf{G} = 0$$

where

$$\mathbf{F} = \square \mathbf{b}' - (\square \mathbf{b})' = \begin{pmatrix} 0 & ie'/c \\ ie'/c & \mu_0 \mathbf{h} \end{pmatrix}$$

and

$$\mathbf{G} = \begin{pmatrix} 0 & \mu_0 \mathbf{h}' \\ -\mu_0 \mathbf{h} & i\mathbf{E}/c \end{pmatrix}$$

are tensors of order 2 under a Lorentz transformation. \mathbf{E}' and \mathbf{h}' are the respective 3 \times 3 duals of \mathbf{e} and \mathbf{h} . All tensor equations are invariant in form in all frames of reference.

The tensor

$$\mathbf{T} = \frac{1}{2}\epsilon_0 c^2 \mathbf{F} \mathbf{F} - \frac{1}{2}\mu_0 {}^{-1}\mathbf{G} \mathbf{G}$$

$$= \frac{1}{2} \begin{pmatrix} \epsilon_0 \mathbf{e}' \cdot \mathbf{e} + \mu_0 \mathbf{h}' \cdot \mathbf{h} & 2ie'\mathbf{h}/c \\ 2i\mathbf{E}\mathbf{h}/c & \epsilon_0 \mathbf{e}\mathbf{e}' + \epsilon_0 \mathbf{E}\mathbf{E}' + \mu_0 \mathbf{h}\mathbf{h}' + \mu_0 \mathbf{H}\mathbf{H}' \end{pmatrix}$$

contains the energy density, Poynting's vector, the momentum density and Maxwell's stress tensor in partitioned form.

Applications may likewise be made to circuit theory, to elasticity where 3×3 stress and strain tensors are defined, and to quantum mechanics, embracing, for example, matrix mechanics and the Dirac wave equation of the electron.

MATRIX MECHANICS

Introduction. This article is a sequel to the article WAVE MECHANICS which appears in this Encyclopedia. We assume that the reader is familiar with the content of that article, which will be referred to here as WM.

The point of view adopted in WM is that non-relativistic quantum mechanics can be formulated entirely in terms of the time-dependent Schrödinger wave equation. While this is true, there are, as remarked in the introduction of WM, situations in which the matrix approach, or a combination of matrix and wave methods, is useful. In the present article, we first discuss some properties of matrices and show how they appear in quantum mechanics. Purely matrix methods are then used to calculate the energy levels and some other properties of the linear harmonic oscillator (WM, p. 773).

Matrices in Quantum Mechanics. A matrix is a square or rectangular array of numbers. Two or more matrices may be added or multiplied in accordance with certain rules. As a simple example, consider the matrix A , which has three rows and four columns; we write it:

$$A = \begin{pmatrix} (1|A|1) & (1|A|2) & (1|A|3) & (1|A|4) \\ (2|A|1) & (2|A|2) & (2|A|3) & (2|A|4) \\ (3|A|1) & (3|A|2) & (3|A|3) & (3|A|4) \end{pmatrix} \quad (1)$$

The twelve parenthetical symbols on the right side of Eq. (1) are the *matrix elements*, and in general are complex numbers which may be functions of some variable such as the time. Two matrices can be added only if they have the same number of rows and the same number of columns; addition then consists in forming the matrix whose elements are the sums of the corresponding elements of the original matrices:

$$C = A + B \text{ implies } (n|C|m) = (n|A|m) + (n|B|m) \quad (2)$$

Two matrices can be multiplied only if the number of columns of the left member of the product is equal to the number of rows of the right member:

$$C = AB \text{ implies } (n|C|m) = \sum_k (n|A|k)(k|B|m) \quad (3)$$

It is apparent from Eqs. (2) and (3) that addition is commutative, but multiplication in general is not.

A *unit matrix* is one which can multiply another matrix and leave it unchanged. It follows from Eq. (3) that it is a square matrix (equal number of rows and columns) that has unity along its principal diagonal (upper left to lower right) and zero elsewhere:

$$(n|1|m) = \delta_{nm} = 1 \text{ if } n = m \text{ and } 0 \text{ if } n \neq m \quad (4)$$

δ_{nm} is the Kronecker δ -symbol. A *constant matrix* $C = c1$ has the number c along the principal diagonal and zero elsewhere. A *diagonal matrix* D has the form:

$$(n|D|m) = D_n \delta_{nm} \quad (5)$$

The numbers D_n are called the eigenvalues of the matrix D .

A matrix A may or may not possess an inverse A^{-1} , which must satisfy both of the relations:

$$AA^{-1} = 1, \quad A^{-1}A = 1$$

The Hermitian adjoint A^\dagger of a matrix A is the matrix formed by interchanging rows and columns and taking the complex conjugate of each element:

$$B = A^\dagger \text{ implies } (n|B|m) = (m|A|n)^* \quad (6)$$

A matrix is *Hermitian* or self-adjoint if it is equal to its Hermitian adjoint: $A = A^\dagger$. It follows from Eq. (6) that only square matrices can be Hermitian. A matrix is *unitary* if its Hermitian adjoint is equal to its inverse:

$$A^\dagger = A^{-1}, \text{ or } AA^\dagger = 1 \text{ and } A^\dagger A = 1 \quad (7)$$

The transformation of a square matrix A into a square matrix A' by means of the transformation matrix S is defined by:

$$SAS^{-1} = A' \quad (8)$$

It is evident that S^{-1} must exist, and that it transforms A' back into A . The form of a matrix equation is unaffected by transformation. Thus the equation

$$AB = CDE = F$$

may be transformed into

$$SABS^{-1} = SC'DE'S^{-1} = SFS^{-1}$$

which is equivalent to

$$A'B' = C'D'E' = F'$$

where the primed and unprimed matrices are related by Eq. (8). This invariance of matrix equations with respect to transformations makes it possible to work with any convenient transformation of a set of matrices without affecting the validity of any results obtained.

It can be shown* that any Hermitian matrix

* The phrase "it can be shown," which appears occasionally in this article, means that the necessary proofs are too long to be given here. They may be found in the books listed as references at the end of the article.

can be transformed into diagonal form by means of a suitable unitary transformation matrix. The diagonal elements of the resulting diagonal matrix are called the eigenvalues of the original Hermitian matrix, as well as of the transformed matrix [see Eq. (5)]. These eigenvalues are easily seen to be real numbers. Since the eigenvalues are the measurable values of quantities represented by matrices, we shall require that physical quantities such as x , p , and H , which must have real eigenvalues, correspond to Hermitian matrices. It can also be shown that the necessary and sufficient condition that two Hermitian matrices A and B can be diagonalized by the same unitary transformation is that they commute, i.e., that $AB = BA$.

Suppose now that the Schrödinger equation [WM, Eq. (14)] is written in the form:

$$H\psi_m = E_m\psi_m \quad (9)$$

where E_m are the energy levels or eigenvalues and the ψ_m are the corresponding *eigenfunctions*. The eigenfunctions can not only be chosen to be normalized [WM, Eq. (19)], so that $\int \psi_m^* \psi_m d\tau = 1$, but also orthogonal to each other: $\int \psi_n^* \psi_m d\tau = 0$ if $n \neq m$. Thus if Eq. (9) is multiplied through by ψ_n^* and integrated over all coordinates, we obtain:

$$\int \psi_n^* H \psi_m d\tau = E_m \delta_{nm} \quad (10)$$

We define the matrix element of the Hamiltonian H in the representation specified by the functions ψ_m as:

$$(n|H|m) = \int \psi_n^* H \psi_m d\tau \quad (11)$$

Equation (10) then shows that when the eigenfunctions ψ_m are used to define the representation, the matrix of H is diagonal, and the diagonal elements are the energy levels of the system.

If some other set of functions ϕ_k , also normalized and orthogonal so that $\int \phi_k^* \phi_l d\tau = \delta_{kl}$, is chosen to specify the representation, the matrix for H would not be in diagonal form. That is, the matrix element

$$(k|H|l) = \int \phi_k^* H \phi_l d\tau \quad (12)$$

would not vanish when $k \neq l$. Now it can be shown that the transformation matrix S , defined by

$$(n|S|k) = \int \psi_n^* \phi_k d\tau \quad (13)$$

is unitary, and transforms the nondiagonal matrix of Eq. (12) into the diagonal matrix of Eq. (11). That is, the transformation equation [Eq. (8)], with the substitution of Eq. (7), may be written:

$$SHS^\dagger = H'$$

or in matrix element form:

$$\sum_k \sum_l (n|S|k)(k|H|l)(l|S^\dagger|m) = (n|H|m) = E_m \delta_{nm}$$

We see then that there are two general methods for finding the energy levels of a system. One is to solve the Schrödinger equation, as in WM, and

determine the energy eigenvalues. The other is to choose a convenient set of functions ϕ_k , use them to calculate a matrix representation [Eq. (12)] for the Hamiltonian, and transform the resulting matrix into diagonal form. The eigenvalues of the diagonal form of H are then the energy levels. It may happen that H can be put in diagonal form directly, without explicit reference to a set of functions ϕ_k or the transformation matrix [Eq. (13)]. An example of this is given in the next section.

Linear Harmonic Oscillator. The linear or one-dimensional harmonic oscillator is described by the Hamiltonian [WM, Eq. (21)]:

$$H = (1/2m)(p^2 + m^2\omega^2 x^2) \quad (14)$$

where $\omega/2\pi$ is the classical frequency of the oscillator. We also know that [WM, Eq. (15)]:

$$px - xp = \hbar/i \quad (15)$$

We then see from the algebra of Eqs. (14) and (15) that

$$(p + im\omega x)(p - im\omega x) = p^2 + m^2\omega^2 x^2 + im\omega(xp - px) \\ = 2mH - m\hbar\omega \quad (16)$$

and that

$$(p - im\omega x)(p + im\omega x) = 2mH + m\hbar\omega \quad (17)$$

If now we multiply Eq. (16) through on the right and Eq. (17) through on the left by $(p + im\omega x)$, we obtain

$$(2mH - m\hbar\omega)(p + im\omega x) = (p + im\omega x) \\ (p - im\omega x)(p + im\omega x) \quad (18) \\ = (p + im\omega x)(2mH + m\hbar\omega)$$

We choose a representation in which H is diagonal, so that, from Eqs. (10) and (11),*

$$(n|H|n') = E_n \delta_{nn'}$$

In this representation, a non-operator number, such as the right side of Eq. (15) or the term $m\hbar\omega$ that is added to or subtracted from $2mH$ in Eq. (18), must be thought of as a constant matrix [defined under Eq. (4)]. Thus if we write the left side of Eq. (18) out in terms of matrix elements, we encounter the term

$$(n|2mH - m\hbar\omega|n') = (n|2mH|n') - (n|m\hbar\omega 1|n') \\ = (2mE_n - m\hbar\omega)\delta_{nn'}$$

It follows that the left side of Eq. (18) is

$$(2mE_n - m\hbar\omega)(n|p + im\omega x|n')$$

and the right side is

$$(n|p + im\omega x|n')(2mE_{n'} + m\hbar\omega)$$

* We use the matrix index n' instead of m , in order to avoid confusion with the oscillator mass.

On equating these two expressions, rearranging terms, and cancelling a common factor $2m$, we obtain:

$$(E_n - E_{n'} - \hbar\omega)(n|p + im\omega x|n') = 0 \quad (19)$$

Equation (19) tells us that either $(E_n - E_{n'} - \hbar\omega)$ is zero, or $(n|p + im\omega x|n')$ is zero, or both. To make use of this result, we write the n th diagonal matrix element of Eq. (16):

$$\sum_n (n|p + im\omega x|n')(n'|p - im\omega x|n) \\ = 2m(E_n - \frac{1}{2}\hbar\omega) \quad (20)$$

Now p and x are physical quantities, and so correspond to Hermitian matrices. Thus $p = p^\dagger$, $x = x^\dagger$, and $(p - im\omega x) = (p + im\omega x)^\dagger$, so that from Eq. (6):

$$(n'|p - im\omega x|n) = (n|p + im\omega x|n')^* \quad (21)$$

Substitution of Eq. (21) on the left side of Eq. (20) shows that each term in the sum is non-negative, so that the right side is also non-negative. From Eq. (19), not more than one term in the sum can fail to vanish; this is the term for which $E_{n'} = E_n - \hbar\omega$, if there is such a term. If there is no such term, or in other words if E_n is the lowest energy eigenvalue, then the left side of Eq. (20) is zero, and $E_n = \frac{1}{2}\hbar\omega$. If there is such a term, then $E_n = \frac{1}{2}\hbar\omega$, and $E_n - \hbar\omega$ is another eigenvalue.

We conclude that the energy levels of the linear harmonic oscillator form the infinite sequence:

$$\frac{1}{2}\hbar\omega, \frac{3}{2}\hbar\omega, \frac{5}{2}\hbar\omega, \dots$$

or:

$$E_n = (n + \frac{1}{2})\hbar\omega, \quad n = 0, 1, 2, \dots \quad (22)$$

This is in agreement with the lowest energy level obtained in WM, Eq. (23).

The diagonal matrix elements of a physical quantity are the *expectation values* of that quantity [see WM, Eq. (20)]. From the preceding discussion, we see that

$$(n|p + im\omega x|n) = 0 \text{ and } (n|p - im\omega x|n) = 0$$

so that, by addition and subtraction of these equations,

$$(n|p|n) = 0 \text{ and } (n|x|n) = 0$$

Thus the expectation value of x and of $p = (\hbar/i)(d/dx)$ is zero for each oscillator eigenfunction. This is easily verified explicitly for the ground state wave function [WM, Eq. (22)]. However, the expectation values of p^2 and of x^2 are not zero, as we now show.

We know from Eq. (19) that $(n - 1|p + im\omega x|n) = 0$, and hence from Eq. (21) that

$$(n|p - im\omega x|n - 1) = 0 \quad (23)$$

We also know from the derivation of Eq. (22) that $(n|p + im\omega x|n - 1)$ is not in general zero, and we set it equal to $2A_n$:

$$(n|p + im\omega x|n - 1) = 2A_n \quad (24)$$

Adding and subtracting Eqs. (23) and (24) we obtain

$$(n|p|n-1) = A_n \quad \text{and} \quad (n|x|n-1) = -iA_n/m\omega$$

Since p and x are Hermitian, we have from Eq. (6) that

$$(n-1|p|n) = A_n^* \quad \text{or} \quad (n|p|n+1) = A_{n+1}^*,$$

and that

$$(n-1|x|n) = iA_n^*/m\omega \quad \text{or} \quad (n|x|n+1) = iA_{n+1}^*/m\omega$$

From Eq. (3):

$$(n|p^2|n) = \sum_{n'} (n|p|n')(n'|p|n) \\ = (n|p|n-1)(n-1|p|n) + (n|p|n+1)(n+1|p|n)$$

since all other matrix elements in the sum are zero. Thus

$$(n|p^2|n) = |A_n|^2 + |A_{n+1}|^2 \quad (25)$$

and in similar fashion

$$(n|x^2|n) = (|A_n|^2 + |A_{n+1}|^2)/m^2\omega^2 \quad (26)$$

Substitution of Eq. (24) into Eq. (20), with the help of Eq. (22), gives:

$$4|A_n|^2 - 2m(E_n - \frac{1}{2}\hbar\omega) = 2nm\hbar\omega$$

so that Eqs. (25) and (26) yield:

$$(n|p^2|n) = (n + \frac{1}{2})m\hbar\omega, \quad (n|x^2|n) = (n + \frac{1}{2})(\hbar/m\omega) \quad (27)$$

Comparison with Eq. (14) shows that the expectation values of the kinetic and potential parts of the energy are equal, and that each is half the energy eigenvalue. The results of Eq. (27) for the lowest state ($n=0$) can be verified by using Eqs. (20) and (22) of WM, normalizing ψ_0 , and performing the integrations.

Conclusion. These two articles, WM and the present one, show in some detail how the Schrödinger wave equation and the matrix theory are related in a particular, relatively simple case. In more complicated situations it may be most convenient to use one or the other of these approaches, or, most often, a combination of the two. The reference books listed below give many examples of the applications of the theory described thus far, and also of its extension to relativistic motion.

MEASUREMENTS, PRINCIPLES OF

Physics in its most fundamental aspect is an experimental science in the sense that speculation is guided by experience; its development depends on frequent comparison between observation and what is deduced from a hypothesis, itself formed to coordinate previous observations. A scientific experiment is a set of events deliberately arranged to reveal as clearly as possible, some regularity in the behavior of physical objects. Compared with other sciences, fundamental physics deals with simple systems, ranging from elementary particles to relatively simple arrangements of atoms. Its experiments are in principle simpler than those of biological science, where the experimenter interferes at his peril with the complicated systems which he studies, or those of cosmology, where the astronomer cannot interfere experimentally and is confined to pure observation of his enormous and remote fields of study. In fact, of course, the theoretical methods of the physicist are sophisticated and the experimental methods are often more elaborate than those employed in other sciences. This elaboration arises from two features of contemporary experimentation, the need to produce extraordinary circumstances, for example, streams of particles having unusually high velocities, and the need to isolate the phenomenon under investigation from all interference. For example, some of the phenomena of the solid state can only be profitably studied in crystalline matter of extreme purity: in many experiments in physics a good vacuum allows particles to travel a long distance without collision or a better vacuum allows a prepared surface to remain for an appreciable time free from contamination by foreign atoms.

Besides fundamental physics, there is a very large field of applied physics, passing imperceptibly into fundamental physics and into engineering; in this field, the systems studied are often man-made devices, and the object of experiments is to obtain data required for design purposes and to examine the performance of finished devices with a view to employing or improving them.

In both fundamental and applied fields, the results of an experiment usually take the form of a set of numerical data which are to be compared with a theoretical calculation, or with another set of experimental data. The value of an experiment may often be judged by the trustworthiness of a numerical result, which in turn depends on the probability of a certain difference (error)

between the result and the result of an ideal experiment in which the required quantity is measured to the exclusion of all disturbance.

The easiest kind of experimental error to estimate and to eliminate is the kind called random; this may be caused by external disturbances or by inherent fluctuations of the kind we shall call noise. It is distinguished by the property that if the experiment is repeated, a different result is obtained, and if it is repeated many times, the difference between the means of groups of repetitions decreases with the number of results in each group. It is clear that the reduction of such errors depends essentially on averaging. There are well-defined experimental and mathematical methods for estimating these errors and reducing them in the most economical way. The accumulation of data for averaging is time-consuming, and since the averaging process necessarily smooths out short-term phenomena, it attenuates the high-frequency sensitivity of the experiment.

A much more serious difficulty arises in determining how far the conditions of an experiment agree with those assumed theoretically to exist. The distinctive skill of an experimental physicist lies in eliminating by design or calculation the systematic error which arises when some unwanted external or internal factor interacts in a consistent way with the system which is being studied. Effects of this kind are not necessarily detected or eliminated by simple repetition of the experiment, and there are no comprehensive rules for designing an experiment free from systematic error. It is sometimes possible to conduct an experiment in such a way that a potentially systematic error appears as a random error which can more easily be detected and eliminated. For example, in photographic photometry, a number of spectra are recorded on a photographic plate, and if the spatial order of the records on the plate coincides with the regular change of some variable in the experiment, a regular variation of plate sensitivity will give rise to an apparently systematic error, which could be avoided by arranging the spectra in random order. Effective techniques for randomizing have been worked out for more complicated situations than this and especially in connection with field trials in agriculture and product control in industry. They are available in books on the design of experiments. As a further application of this principle, if the characteristics of an experiment are liable to change with time, it is undesirable to change a variable of the experiment in a monotonic way since the drift then appears as an undetectable systematic error. It would have been apparent if variations had been made in random order. Apart from this possibility, external disturbances may sometimes be eliminated by means of isolation as discussed below; external conditions may be varied over as wide a range as practicable in order to detect unsuspected interactions, and conditions may then be held as nearly constant as possible during the important observations. Of course, the experiment must be carefully and repeatedly reviewed theoretically to search for possible disturbing

effects, and subsidiary experiments or deliberate variations of the main experiment may be required to detect them. In the final resort, it may be possible to invent a radically different experiment to measure a required quantity or substantiate a theoretical conclusion, the hope being that quite different systematic errors will then be encountered. It is true that most of the fundamental ideas of physics and most of the important numerical quantities used in it rest upon broad experimental foundations rather than single experiments. From time to time, single experiments assume a crucial status, decisive between two theories, as the Bothe-Geiger coincidence experiment of the thirties decided between the electromagnetic and the charged-particle views of penetrating cosmic rays, or the experiments of Wu, Ambler and others, settled the non-conservation of parity. However, such experiments have always appeared, in retrospect at least, as fitting into the broader background of experimental fact.

Every event in an experiment is in principle coupled with events in the outside world, and this coupling may lead to systematic or to random error. The coupling may be mechanical, thermal, or electromagnetic, or it may involve the incursion of radiation or of nuclear particles. Time variations of these disturbances are more important than the steady components, which can be eliminated by proper measurement techniques. The time variations are sometimes produced by the spontaneous variations (fundamental noise) associated with the disturbance. For example, the effective sensitivity of thermal detectors of radiation may be limited by the fluctuations in the (parasitic) exchange of radiation between detector and its immediate surroundings, and the fluctuations can be reduced by operating at a low temperature. Not all time variations are of this fundamental type, and it may be necessary to stabilize the environment (e.g., temperature, pressure, electrical supplies) by the established feedback techniques.

We now review some of the techniques for isolating an experiment from the disturbances considered above.

(a) *Attenuation of mechanical vibrations:* traditionally this is achieved by special building construction, placing mechanically critical experiments on ground or subterranean floors, providing special foundations not closely coupled to the rest of the building; these measures are applicable to astronomical telescopes, but their importance in the physical laboratory is probably decreasing. Mechanically vulnerable assemblies can be isolated by systems of masses, springs and dampers designed as mechanical filters, but there are practical difficulties in securing high attenuation at low frequencies. Sometimes attenuation is required in a particular direction, and vibrations in other directions are relatively unimportant; the design of an antivibration support may then be simplified, as where an antivibration mounting is provided for a rotational instrument like a galvanometer. Finally, rotational disturbances of a

suspended system can be produced by sideways accelerations if the rotating system does not satisfy the conditions for dynamic balance, and these conditions must be satisfied to improve steadiness.

(b) *Thermal effects* on measuring equipment may involve the actual temperature of a particular element, in which case thermostatic devices are required, and one of the most precise is the use of a phase-equilibrium bath, i.e., ice or some other solid in equilibrium with its liquid. But thermal effects may be produced by the appearance of temperature *differences* producing mechanical deformation, thermoelectric voltages, or changes in relative values of resistances. The reduction of these differences demands good thermal transfer among the parts themselves and poor thermal transfer between the parts and the external disturbances, so that insulation must be combined with good conducting layers, or even more effective, stirred liquid baths.

(c) *Magnetic systems* are protected from disturbances in two different ways: by shielding and by astatic design. The former involves layers of soft magnetic material, but it must be remembered that the materials of highest permeability (e.g., the permalloys) saturate in quite weak fields and then produce little or no attenuation of disturbances. They must generally be used within outer shields of substances like soft iron. The second method depends on constructing the measuring system (which may consist of suspended magnets or wound coils) in such a way that the effects of a disturbing field, uniform in space, neutralize one another while the effects to be measured do not. It is clear that the sensitivity to the gradient of a disturbing field depends on detailed design, e.g., the nearness of two coils, and that more complicated systems could be used to remove derivatives of higher order.

(d) *Electrostatic and electromagnetic disturbances* are often easy to eliminate by metallic shielding, but the effect of very small holes in the shielding may be appreciable. The effects are worst in electronic devices of high impedance, particularly electron tubes used as electrometers, which can rectify and detect high-frequency disturbances. Such sensitive equipment may require metallic shielding of nearly gastight quality or, indeed, complete double shielding. Furthermore if the sensitive circuit forms a loop coupled with a varying magnetic flux, disturbances will be induced in it in spite of metal shielding of finite conductivity, and such loops must be avoided.

When the experiment has been protected from disturbances, the next step in measurement technique is to eliminate the steady or slowly varying effects which are still present; the simplest example is that of taking the zero of an instrument before and after a reading. If these readings are taken in a regular time sequence, a linear drift can be completely eliminated. It is important to arrange the apparatus so that "on" and "off" readings, more generally "condition A" and "condition B," may be alternated *rapidly* and

with *minimal disturbance* of conditions. This is often a distinctive feature of a well-designed measurement technique. A fundamentally similar but more sophisticated procedure is obtained by automatic alternation of conditions A and B, followed by automatic separation and subtraction of the results of the two conditions. The simplest example is the use of a "chopper" amplifier to measure quasi-steady voltages; a vibrating switch or its equivalent interrupts the input to an amplifier which is required only to amplify the alternating component and which can be free from long-period drift. The output of the amplifier is measured by a rectifying instrument or, more advantageously, by an instrument which is sensitive only to components properly related in phase to the alternations of the input.

Developments of this technique are far reaching, and there are two important extensions of it. The output obtained can be used to control condition A or condition B until they are equal; this is an application of the feedback principle. Furthermore, since the final output is a zero-frequency measure of the difference between A and B, it can be integrated over a long time by electrical, electronic or electromechanical methods (condenser charging, feedback integrator or integrating motor), and noise-type fluctuations, alternating disturbances outside an extremely small frequency band, and disturbances common to A and B—can be eliminated to a spectacular degree. The accuracy of every measurement is limited by fundamental or fluctuation phenomena which it is convenient to call *noise*, though often it is not practically necessary or technically possible to take the elimination of other disturbances to the point where this noise becomes limiting. If we are concerned with the measurement of a quasi-steady quantity, noise can always be removed by time-averaging, though this process will attenuate small, nonrecurring transitory events, and these must remain permanently masked by the noise.

The most fundamental limitations of this kind arise from the "uncertainty" limitations of quantum mechanics, since it is not possible to define simultaneously and accurately the variables belonging to certain canonical pairs such as energy and time, momentum and position. A practical example of this limitation is the finite width, in terms of quantum energy or spectral frequency, of a spectrum line, arising from an excited state of finite life. This limit ($\sim 10^{-7}$ in many cases) is reached in the determination of a wavelength as a standard of length, but there is no reason why the length should not be defined to greater accuracy by the mean wavelength emitted from a great many atoms. In fact, the present experimental limit lies in finding a light source in which the systematic disturbing effect of fields external to the atoms is sufficiently reproducible.

Many measurements in practice are affected by fluctuations coarser than the quantum limit, and important examples are thermal fluctuations and the effect of the discrete (particulate) nature of matter and electricity.

Every degree of freedom determining the configuration of a system is associated with some energy, which appears as fluctuations of the appropriate coordinate. In principle, the statistics of these fluctuations must be calculated from quantum theory, but in many cases of practical importance, the average kinetic energy associated with a particular coordinate has the equipartition value $\frac{1}{2}kT$, and an approximate value of the uncertainty in amplitude can be calculated from this result. In practice, thermal fluctuations are most often encountered in electrical circuits because electronic devices have a high sensitivity extending over a wide frequency band. The fluctuation noise can now be put in the form of an alternating voltage in series with each resistor, distributed over all frequencies in accordance with the formula $E^2 d\nu = 4kTRd\nu$ (non-quantum approximation for frequencies such that $h\nu \ll kT$). Here E^2 denotes the distribution function for the squared voltage at frequency ν , T is the temperature and R the resistance. The effect on any circuit can be calculated from this result. It is apparent that the total noise voltage increases with the frequency bandwidth to which the system responds, so that it can be reduced in a system which has a long time of response, either because it responds only to low frequencies or because its response is narrowly selective. The phase-sensitive rectifier technique discussed above is a method of securing such a narrow response. Rapidly transient phenomena are, of course, excluded by any such system. It can be shown that if we can average our observations for a time τ , the relative accuracy varies as τ^{-1} . Thermal noise can be reduced in appropriate circumstances by reducing the temperature of the resistances involved, but the noise voltage distribution is then appreciably modified by quantum effects and does not disappear at absolute zero. It will be noted that thermal noise is explicitly connected with the resistive elements of a circuit. It can be reduced by using systems of amplification (parametric amplification) which do not in principle require resistive elements or by reducing the dissipative (resistive) element of a system by a properly phased feedback device.

In addition to the thermal noise, fluctuations can arise statistically from the passage of discrete electrons in a circuit, the full calculated value being observed in a saturated diode or in a photocell. The fluctuations are suppressed by the conduction mechanism of a metallic conductor or in part by the space charge of a triode or pentode, though in the pentode there is a new source of noise in the distribution of electrons between anode and screen. Noise of this kind (shot noise) is a major limitation in practical high-frequency measurements, but it is to some extent amenable to reduction by circuit techniques. The corresponding effect in a photocell is due to the finite rate of reception of quanta (N per second) and the corresponding rate of emission of electrons ($N\epsilon$ where ϵ is the cathode quantum efficiency), and it is inescapable. Furthermore, it is overlaid by the fluctuations of the "dark current" which may flow in the absence of incident quanta. This

dark current can be reduced by technical measures, and this must be done if the accuracy of the measurement of weak light is to be maximized. A further type of fluctuation, additional to thermal noise and shot noise, occurs in semiconductors and in the emission from most technical cathodes. It is not yet completely explained in theoretical terms; the squared distribution function is not uniform and increases rapidly at low frequencies; when this "excess noise" is present, it is desirable to "put the signal where the noise is not," i.e., to reduce the response of the measuring system at low frequencies and to make the signal appear at higher frequencies if the signal frequency can be chosen arbitrarily as in the case of a "chopper" detector or amplifier.

MECHANICS

The beginnings of the science of mechanics goes back to the Greeks inasmuch as they had derived some fundamental ideas on levers, vibrations of strings and on hydrostatics. However, not until the sixteenth century did mechanics make a real beginning whose progress has continued to the present day. Two great names are associated with the mechanics of the sixteenth and seventeenth centuries, namely Galileo Galilei in Italy and Sir Isaac Newton in England. Galileo (1564-1642) was essentially the one who insisted on the importance of observations of nature, of combining experiments and observations with careful thought, as opposed to the Aristotelians who at that time insisted that all knowledge came by thought alone. Many of the experiments that Galileo performed and the conclusions drawn from them are given in a book entitled "Two New Sciences," which, though written in a dialogue form, is still worthy of being read.

Following Galileo came another "natural philosopher," Sir Isaac Newton (1642-1727), who was one of the greatest of all time. It is interesting that the word "scientist" did not come into use until the middle of the nineteenth century, though the term "natural philosopher" is still used in some of the older universities. Newton's contributions in mathematics and physics were unique, for he invented the calculus and discovered the law of gravitation and the laws of motion. It is somewhat difficult to appreciate all that Newton did for the world. More than anyone else he ushered in the modern scientific era. The heavens were a region with its own particular laws, a region where speculation had relatively free reign. Newton changed all this. He applied to the planets the laws of motion, which were applicable to bodies on the earth, and he found he could account for the motion of the planets with remarkable accuracy.

So strong was the faith in the Newtonian principles that when the planet Uranus appeared to be deviating from its predicted orbit the assumption was made that there must be another planet as yet unknown. The position of this unknown planet was calculated and thus Neptune was found in 1846. Such was the success of the Newtonian conception of the universe.

Newton left the world a mechanical universe. Forces produced changes in motion between the sun and the planets just as they did between objects on the earth. It was the Newtonian idea that forces produced changes in motion in contradiction to the then current Aristotelean idea that force was required to keep motion going. Newton tried to be most careful in denying any "cause" in these laws of motion. He was trying to give a description of motion in terms of the laws. In his famous book "The Mathematical Principles of Natural Philosophy," usually referred to as "The Principia," Newton presents the scope of his work in mechanics, and what a grand scope it is. He not only discusses the motions of objects on the earth but the motion of the planets as well; the precession of the equinoxes, the tides and other problems in fluid motion.

The scientific caution which Newton showed in the Principia is illustrated by the following quotation: "For I here design only to give mathematical notion of those forces without considering their physical causes and seats." In another context he says: "You sometimes speak of GRAVITY as essential and inherent to matter. Pray do not ascribe that notion to me; for the cause of gravity is what I do not pretend to know."

Though there were no new physical principles, associated with mechanics, developed during the eighteenth and nineteenth centuries, there was much mathematical development. The Lagrange equations of motion are an elegant and different expression of the Newtonian equations of motion. Where Newton was concerned with forces, Lagrange was concerned with energy. In his "Mécanique Analytique" (1778), Lagrange showed how a mechanical problem could be solved on the basis of pure calculation without appealing to physical or geometrical considerations provided the kinetic and potential energies of the system were given in the appropriate form. Lagrange says in the preface "The reader will find no figures in the work. The methods which I set forth do not require either constructions or geometrical or mechanical reasonings; but only algebraic operations, subject to a regular and uniform rule of procedure." Considerable contributions to theoretical mechanics were also made by Sir William Rowan Hamilton (1805-1865) and C. G. J. Jacobi (1804-1851) together with a number of others: Gauss, Poisson, Poincaré and Mach.

Towards the middle of the last century, the principle of conservation of energy was firmly established on experimental grounds. This has been of enormous importance, for as different forms of energy have been recognized they have been seen to fit into a much wider perspective.

In the present century there has been the development of the theory of RELATIVITY by A. Einstein (1879-1955), important in the region of velocities close to the velocity of light, and of the QUANTUM MECHANICS applicable to the phenomena on the very small scale found in atoms.

It is obvious that motion is movement of some object relative to some other object. Newton recognized this in the Principia, and on the considerations of rotational motion, he found it necessary to postulate absolute space and absolute time. For motion at constant speed in a straight line it readily follows from Newton's laws that it is impossible to perform any physical experiment which can detect this motion. However, when the motion is accelerated, forces are required and the presence of the acceleration is readily determined. If a horizontal circular platform is turning with constant angular speed about a vertical axis through its center, then an observer on the moving platform experiences a centrifugal acceleration (see ROTATION—CIRCULAR MOTION). Also if he moves along a radius he experiences a sidewise acceleration called the CORIOLIS ACCELERATION. These accelerations are easily accounted for in terms of a rotating reference system. The earth is such a system and the centrifugal acceleration is shown in the systematic variation of the acceleration of gravity with latitude. For recognizable aspects of the Coriolis acceleration on the earth one has to examine large scale motions. The fact that the winds do not go directly from high pressure regions to low pressure ones in cyclones and anticyclones is readily explained by the Coriolis acceleration and force.

A major revision of thought came in mechanics in the present century when Einstein applied the theory of RELATIVITY to reference systems moving with constant velocity relative to one another. TIME and distance were not the same in the different systems though the speed of light was assumed to be constant in all the systems. This brought changes in mechanics which become appreciable when the speeds approach that of light, about 186,000 miles/sec. It is only in the realm of atomic and nuclear physics that speeds approaching this are encountered. In the macroscopic world of automobiles and airplanes the Newtonian mechanics is still applicable with considerable accuracy.

Mechanics has influenced many of the theories in other branches. It was a natural tendency to account for phenomena in mechanical terms whenever possible. Forces were experienced in electrical phenomena, and it was from the forces that entities such as electric charges were postulated. Vibratory motion, such as that undergone by an object hanging on a vertical spring, is used in explaining the scattering of light and x-rays.

There are two very important CONSERVATION LAWS in mechanics, namely conservation of momentum and conservation of energy. The expressions for these conservation laws, but not the principle of the laws, changes when the speeds of the objects approaches that of light. Then the

Einstein relativistic expressions must be used. For angular motion there is a corresponding law of conservation of angular momentum. Then there is the law of conservation of energy, a law which, when it includes mass m , as a form of energy E , by the relationship, $E = mc^2$, brings together two former conservation laws, namely the laws of conservation of mass and energy. The letter c indicates the velocity of light.

Thus we see that mechanics has a great theoretical structure and is also of great importance in the everyday world of machines and bridges. It has influenced all the sciences and today is as important as it ever was.

MEDICAL PHYSICS

That physics has an important place in medicine can scarcely be denied. A physician's first move in examining a patient is to measure his temperature, count his pulse, listen to his heart sounds and take his blood pressure. Only much later does the physician get around to chemical and laboratory tests. Yet every hospital of any stature has a laboratory or a department of clinical chemistry. Laboratories of clinical physics are virtually nonexistent. While physics plays a large role in medical diagnosis and treatment, physicists have largely neglected the field.

Some of the earliest applications of the principles of physics to problems in medicine were in the fields of optics and sound. An early contributor was H. L. F. von Helmholtz, a physician as well as a physicist. His work in physiological optics and that on the sensations of tone are considered classics. Even earlier, J. L. M. Poiseuille, a French physician and physicist, seeking a better understanding of the flow of blood, studied the flow of water in rigid tubes. His work not only contributed to physiology but also established an important relation in the physics of viscous fluids.

With the intensive development of the sciences of physics and medicine in the latter part of the nineteenth century, the two drew further apart. This period also saw rapid development in the science of physiology which is concerned not only with body chemistry but also with physical processes in the body. Clinical physiology abounds with such concepts as the pressure-velocity relationships in the flow of blood, the mechanics of the cardiac cycle, the work of breathing, gas exchange in the lungs, voltage gradient in cellular membranes, and cable properties of nerves, to

name but a few. These concepts have, of necessity, been worked out by scientists with training and experience in the basic biological and clinical procedures. Physicists have been inactive in the field and have made very little contribution to its development. But there is a growing awareness among physiologists of the importance of physical principles and the need for precise statement of physical law. An example of this conviction is the 18th edition of Howell's Textbook of Physiology which carries the title, "Medical Physiology and Biophysics."¹

A phenomenon of the mid-twentieth century has been the development of interdisciplinary fields of science. BIOPHYSICS combines the most fundamental of the biological and physical sciences. It has had an extremely rapid growth, with something like 30 to 40 university Departments of Biophysics in America alone. Its emphasis has been on the application of physical principles to all aspects of biology—cellular, botanical, zoological as well as clinical.

An even more recent phenomena has been the development of biomedical engineering. Its basis has been the application of the tremendous developments in electronics to medical measurements and instrumentation. In fact, the field is frequently referred to as biomedical electronics. Such recent developments as vector electrocardiography, implantable pacemakers for the heart, and intensive-care physiological monitors and recorders are examples of the impact of electronics on medicine. While these fields border on medical physics, none are concerned primarily with the application of physical principles to clinical problems. Yet they compete so effectively with medical physics that it is difficult to delineate the boundaries of the latter.

The discovery of x-RAYS by Roentgen in 1895 had an immediate impact upon medicine. Within a few months, the new rays were used both diagnostically and therapeutically. Indirectly, their application set the stage for the development of medical physics. Therapeutic application of x-rays raised questions concerning their quality and quantity—both of which are important in accurate dosimetry. Evaluation of early successes and failures indicated the importance of the proper distribution of dose between neoplasm and normal tissue. The physician turned to the physicist for assistance. The late Otto Glasser was one of the early radiological physicists; he and Fricke in 1924 constructed an air wall ionization chamber for the measurement of radiation dose.² Their construction eliminated some of the nonlinear effects due to quality, i.e., photon energy distribution, in the evaluation of biological response. Other early workers in America were Edith Quimby³ and the late G. Failla. In England, L. H. Gray and W. V. Mayneord were active. In 1936, Gray proposed the Bragg-Gray formula for determining the absolute amount of energy delivered to a medium from ionization measurements.⁴ The work of Fricke, Glasser, and Failla along with that of L. S. Taylor⁵ and others contributed to the establishment in 1928 by the

Second International Congress of Radiology of the roentgen as a unit of radiation dose based on the amount of ionization generated in a standard volume of air. The use of higher energies and ionizing radiations other than x-rays led during the 1950's to the abandonment of the roentgen as a unit of absorbed dose. Dissatisfaction with the roentgen was also due to a growing realization that biological response was more nearly related to the energy absorbed in a medium. The Bragg-Gray formula permitted the calculation of absorbed dose in a medium, and the work of J. S. Laughlin⁶ established the dosimetry of high-energy radiations in energy units by calorimetric methods. The International Commission on Radiological Units in 1956 adopted the *rad* as the unit of absorbed dose defining it as being equal to an absorption of 100 ergs per gram of material. The roentgen was retained as a unit of exposure dose for x-rays below 3 MeV, i.e., a measure of the intensity of a beam of x-rays to which a material might be exposed.

While radiological physics is clearly a part of the broader discipline of medical physics, it included in the early days practically all that was organized of the later subject. In 1943, Otto Glasser was persuaded to edit an encyclopedia on medical physics.⁷ It has since gone through three editions. It treats the physical aspects of the principal, medically oriented subjects including anatomy, dermatology, hematology, neurology, orthopedics, pathology, radiology and surgery, to name but a few, and provides a good survey of the scope of the field.

Until recently there has been no organization of workers in the field of medical physics. Radiological physicists were associate members of the North American Radiological Society, naturally dominated by radiologists. First in Britain, (the Hospital Physicists' Association) and later in America, specialty groups have been organized. The American Association of Physicists in Medicine brings together those physicists working in hospitals and medical schools and interested in an understanding of the physical side of medical problems. The membership has been largely drawn from those working in the area of radiological physics, but a growing interest in the broader area pertaining to all of medicine can be discerned. The organization cooperates with its British counterpart in the publication of a journal—*Physics in Medicine and Biology*. A further indication of the developing awareness of this field is the organization of the First International Conference on Medical Physics which was held at Harrogate, England in September 1965.

One last word about a related field: Radiation protection was in the early days a part of radiological physics. In America, L. S. Taylor was active for many years at the Bureau of Standards in setting up guidelines for protection from radiation. During World War II, the Manhattan Project required large numbers of workers in the field of protection, and the term **HEALTH PHYSICS** was introduced. Since the war, the field has grown with the growth of the area of atomic energy. The

Health Physics Society is a large and growing group with many local chapters and an international organization. The field seems, though, to be becoming more closely aligned with the area of public health than with clinical medicine.

That physics will play an increasingly important role in medicine cannot be challenged. But whether physicists will truly create a discipline of medical physics or whether that role will be played by physiologists, biophysicists, biomedical engineers or others remains to be seen.

METALLURGY

The metallurgical industry is one of the oldest of the arts, but one of the youngest of the subjects to be investigated systematically and considered analytically in the tradition of the pure sciences. It is only in comparatively recent times that any fundamental work has been carried out on metals and alloys, but there are now well-established and rapidly growing branches of science which are related to the metallurgical industry.

Process Metallurgy. Process metallurgy, or the science of extracting metals from their ores, is broadly divided into two groups.

Ferrous. This branch is concerned with the production of *iron* (normally from iron ore, with coke and limestone in a blast furnace) and its subsequent refining to *steel*, by oxidizing the impurities either in an "open hearth" furnace by means of an appropriate slag on the surface or in a "converter" by blowing air through the molten iron. The most striking recent development in this field has been the increasing use of pure

gaseous oxygen in steelmaking, with a resultant improvement in efficiency, rate of production, and quality of product.

Non-ferrous. This is concerned with the production of the remaining metals. Those manufactured in greatest quantity include aluminium, copper, nickel, zinc, magnesium and tin, with titanium being an important newcomer in view of its low density, high melting point (1670 °C) and resistance to corrosion. The precious metals, and the "refractory metals" of very high melting point (e.g., tungsten and molybdenum) are other important families.

Shaping of Metals. This may be carried out in three main ways:

Casting. Although most metals are initially cast into *ingots*, which may be subsequently forged to the desired shape, many alloys are designed to be cast into their final shape by pouring the molten alloy into an appropriate mold. These may be sand molds if only a small number of objects are required, and very massive castings (e.g., over 100 tons) may also be produced in this way. A permanent mold, or die casting, is employed if large numbers of the object are required (particularly in alloys of low melting point, such as zinc-based alloys) and high dimensional accuracy can be achieved by these means.

Forging. This entails shaping of the metal by rolling, pressing, hammering, etc., and may be carried out at high temperatures, when the metal is soft (hot working), or at lower temperatures (cold working), where the deformation leads to progressive hardening of the metal (work hardening). In contrast with castings, forgings usually exhibit differing physical and mechanical properties in different directions, due to the directional nature of the shaping operation.

Much modern research in physical metallurgy is concerned with investigating the plastic flow and work hardening behavior of metals and alloys. Metal crystals yield plastically at stresses several orders of magnitude lower than the theoretical value for the deformation of perfect crystals: this discrepancy is accounted for by the presence of imperfections known as "dislocation lines" within the crystals. Plastic flow takes place in metal crystals by "slip" or "glide" in definite crystallographic directions on certain crystal planes, due to the movement of dislocation lines under the applied stress. Dislocations multiply and entangle as deformation proceeds, thus making further flow increasingly difficult (work hardening)—the density of dislocations rising from about $10^7/\text{cm}^2$ in soft (annealed) metal to about $10^{12}/\text{cm}^2$ in work-hardened material. Such crystal defects can be studied by x-ray diffraction and by modern electron micrographic means.

Powder Metallurgy. This is a method of shaping by pressing finely powdered metal into an appropriately shaped die. The "green compact" thereby produced is of low strength and is subsequently heated in an inert atmosphere ("sintered"); the pressing and sintering may be repeated until strong, dense products are obtained. The technology was first developed for metals which were

of too high a melting point for conventional casting and forging methods, and tungsten lamp filaments were first produced by this means. Other refractory metals and hard metal-cutting alloys may be thus shaped, and some magnetic and other special alloys are prepared in this way by suitable blending of powders, which avoids any contamination that may be associated with the melting process. The pressing and sintering conditions may be arranged to leave some residual porosity in the structure of, for example, bronze bearing alloys. The pores are filled with oil, thus producing the so-called oil-less bearings which can operate without further lubrication.

Joining. Rivetting, soldering and brazing (in which metal components are joined by means of a layer of a low-melting alloy), and welding are the important methods of joining metals. *Weldability* is often the critical factor in the selection of an alloy for a given purpose, since the metallurgical changes produced by localized heating are often associated with the development of deleterious properties at, or adjacent to, the weld.

Alloy Constitution. Phase equilibria in alloy systems are represented on *phase diagrams*, which are experimentally established by thermal analysis, microscopical, and x-ray diffraction methods. Phase diagrams are invaluable in the interpretation of the structures of alloys observed under the microscope.

The microstructure of an alloy (and hence its properties) will be determined not only by its composition, but also by its thermal and mechanical history. Of particular importance is the metallurgical control of the mechanical properties of an alloy by *heat-treatment*, which affects the distribution of the phases present. Hardness, for example, will depend upon the state of deformation (i.e., the density of dislocations) and upon the composition of the alloy. Pure metal crystals can be hardened by other atoms in solid solution (solute hardening) as well as by finely dispersed particles of a hard second phase (precipitation, or dispersion hardening) which are effective in impeding the motion of dislocations when the crystal is stressed. The relationship between the microstructure and properties of metals and alloys is thus of fundamental importance and is a field of intense scientific activity.

Although many common alloys were not developed scientifically, there is a considerable theory of alloy developing, springing from empirical rules and principles (notably those due to W. Hume-Rothery) which have generalized the facts and enabled predictions to be made. The early theories of the metallic state, due to Drude and Lorentz, and later to Sommerfeld were developed and discussed by N. F. Mott and H. Jones in their book "The Theory of the Properties of Metals and Alloys." Although during the last decade the early electron theory of copper alloys has gradually been destroyed by recent theoretical and experimental work, a great increase in our knowledge of transition metals and their alloys has taken place, and some signs of general principles have begun to appear, although there is yet

little theoretical knowledge enabling one to calculate properties or structures of alloys from fundamental principles.

The Effect of Environment Upon the Behavior of Metals.

Low Temperature. Some metals and alloys exhibit a spectacular change in mechanical behavior with decrease in temperature. Many metals of body-centered cubic crystal symmetry (e.g., iron and mild steel) which are tough and ductile at ordinary temperature become completely brittle at subzero temperatures, the actual transition temperature depending upon the metallurgical condition of the alloy, the state of stress, and rate of deformation. Some metals of hexagonal symmetry (e.g., zinc) exhibit this effect, but metals of face-centered cubic symmetry (e.g., copper) remain ductile to the lowest temperatures. This transition in behavior is clearly of critical importance in the selection of materials for low-temperature application.

High Temperature. Apart from problems of oxidation (discussed below), metals tend to deform under constant stress at elevated temperatures (the deformation is known as "creep"), and creep-resistant alloys are designed to provide strength at high temperatures. These are essentially alloys in a state of high thermodynamic stability, usually containing finely dispersed particles of a hard second phase which impede the movement of dislocations.

Fatigue. Metals break under oscillating stresses whose maximum value is smaller than that required to cause rupture in a static test, although many ferrous alloys show a "fatigue limit," or stress below which such fracture never occurs, however great the number of cycles of application. The phenomenon is associated with the nucleation of submicroscopic surface cracks in the fatigued component early in its life, which initially grow very slowly. Eventually a crack grows until the effective cross section of the piece is reduced to such a value that the applied stress cannot be supported, and rapid failure occurs.

Oxidation and Corrosion. Apart from the noble metals, when metals are heated in air, they owe their oxidation resistance to the presence of impervious oxide films of their surface, and those which develop porous oxides (e.g., the refractory metals tungsten and molybdenum) oxidize very rapidly at high temperatures. Oxidation resistant alloys are designed to maintain a protective film under these conditions.

Corrosion occurs under conditions of high humidity or immersion in aqueous media. The phenomenon can be interpreted electrochemically—local anodes form at the region of metal dissolution, and local cathodes form where the electrons are discharged. "Galvanic corrosion" is encountered where dissimilar metals are in electrical contact under these conditions. Of particular importance is the *conjoint* action of stress and corrosion, where "stress corrosion" or (under fluctuating stresses) "corrosion fatigue" cracking may be encountered, in situations where no failure would occur under the action of the stress

or the corrosive environment applied separately. Electrochemical principles are applied in the protection against corrosion.

METEOROLOGY

The theme of meteorology over the past two decades has been expansion; expansion in all its aspects; expansion at accelerating pace. Meteorology has moved into an era of quantization and specialization. The reasons for this growth are not hard to find. The world is making ever greater use of its atmosphere and must know more about its nature. At the same time, the modern electronic tools for probing the atmosphere in depth have become available. As a result there are more data, more interest, more research, and more services than ever before.

Traditionally meteorological data were gathered by surface observers. Thirty years ago regular observations of the upper atmosphere began on a regular basis by means of balloon soundings using radio telemetry to transmit the data to the ground station. This proved to be the beginning of a veritable explosion in the sampling of the atmosphere. Instrumentation and balloon quality have steadily improved, but the network stations are now approaching the altitude limit of 32 km. Beyond this level, the rocket has replaced the balloon as the vehicle for sampling to about 60 km. Density, temperature and wind are being measured by a small but growing network. Beyond 60 km, rocket data are limited by lack of instruments capable of measuring under these conditions. This will soon be overcome.

At a still higher level, the satellite operates as an observing platform. Sensors on this platform measure various types of radiation. From radiations in the visible bands come the familiar and impressive pictures of clouds and terrain. High-resolution infrared radiation is providing pictures

on the dark side of the world as well as measurements of the temperature on the earth, clouds, and atmosphere. Other bands tell how much radiation is being removed by water vapor and other absorbers and, hence, provide a measure of the quantities and distributions of these constituents. The satellite samples equally well over difficult terrain and populated areas, and it promises to provide answers to one of the scientists' great problems—that of obtaining adequate data on a global scale. It also provides a direct method of obtaining the radiational balance of the earth and atmosphere, a factor of fundamental importance in the energy budget of the earth-atmosphere system and a vital parameter in the general circulation and in long-range forecasting.

Meteorology requires data over wide areas as well as to great heights and here again progress has been great. Observational instructions have been standardized on a global basis and data are freely exchanged. Advances in speed of transmission have increased the volume of data exchanged, and the evidence is that the speed will increase further by many orders of magnitude. Processed data are being exchanged also in numerical, pictorial, and digital forms. In addition to the original radio and teletype, there is the facsimile for visual presentations and the communications satellite which will be important in future global networks.

The tools of measurement have undergone equally impressive development. The radiosonde is no longer restricted to measurement of the traditional pressure, temperature, humidity, and wind. It may also measure radiational flux, ozone distribution, and other factors in the upper air. Radar has come of age as a tool of great power in probing the secrets of cloud and precipitation physics. Micrometeorological systems consisting of thermometers and anemometers measure the parameters important for analysis of turbulent flow and diffusion. They also exemplify the growing tendency to create systems which feed out processed rather than raw data, in this case in the form of statistical data in digitized form.

With the vastly increased capacity for obtaining data has come an increased capacity for digesting it. Data which may have future value are stored, often in the form of punched cards. However with increasing masses of data even the storage of punched cards is a problem, and even more concise forms are being developed. Data, particularly analyzed data, are being stored in digitized form on magnetic tapes. This makes them readily available for analysis on an electronic computer. With this sort of capability, the whole approach to research is undergoing change. In many areas, the analysis by electronic computer has become the normal approach. Synoptic analysis and prediction is rapidly moving into that class.

As one might expect with the avalanche of new data, research into the structure and behavior of the atmosphere has been experiencing a corresponding development. This is exemplified

by the growth of institutions for research and teaching in meteorology. Thirty years ago, there were in the world only a few universities active in meteorology. Today there are 20 to 30 in the United States alone, and there are many more in certain specialized areas of the science. This period has seen the manyfold increase in direct participation by the governmental agencies in meteorological research. Journals to publish the resulting research have matured and multiplied. The private meteorological consultant has come into his own. Many have built medium-sized firms providing a large amount of specialized service including research under contract to private companies as well as to the government.

Thirty years ago, meteorology largely consisted of a semiquantitative science concerned with the synoptic scale motions of the atmosphere, those of importance to forecasting for the next 48 hours, and certain basic physical principles. This picture has changed completely in the intervening years. Gone is the simple flow concept of the atmosphere, and in its place is an atmosphere of almost unbelievable complexity. In place of the synoptic scale pattern of wave motion in the atmosphere, we have a hierarchy of scales. These include the hemispheric long waves, or Rossby waves, in the westerly flow having wavelengths of the order of 5000 km, and the synoptic scale of wavelength of the order of 1500 km. Then follows the mesoscale, phenomena of the order of 10 to 50 km, and the microscale which involves motions of the order of a few meters. According to Kolmogoroff, the driving energy of the atmosphere is transferred from one scale of motion to another of lower scale. Large-scale motions break down into smaller motions which themselves break down into still smaller motions. Thus energy cascades down the scale, the limit being reached when energy is absorbed into motions of the molecules showing up as heat.

The middle-latitude westerly stream of air, formerly thought to be a broad steady flow, is organized into two or more jet streams; narrow streams of air concentrated at tropopause level and extending around the world with speeds up to 100 m/sec. The jet streams generally meander northward and southward outlining a more or less regular wave pattern of the order of 90° longitude wavelength. These Rossby waves move only slowly. Ridges in the system correspond to warmer than average air and troughs to colder. Thus these systems are the key to extended range forecasting, forecasting of the order of 5 days in advance.

The synoptic scale motions were, of course, much studied in earlier years. Nevertheless, with better upper air data and knowledge of motions in other scales, advances are still being made. Perhaps the most significant advance in both the hemispheric scale and the synoptic scale has been made possible by the electronic computer. The equations of motion of the atmosphere have been known since the early days of the science. However, these equations are nonlinear. A functional solution is not possible. A numerical solution is

possible under simplifying assumptions but only if facilities are available for extensive calculation. The electronic computer has made this possible. Research over the past 15 years has shown which assumptions are necessary to produce representative mathematical models of the atmosphere amenable to solution. As it turns out, quite useful results can be obtained by a very rigid restriction, the assumption of a barotropic atmosphere. In such an atmosphere, all levels behave in exactly the same manner so that this model can only approximate the real atmosphere at one level. This level is approximately 4.5 km altitude. It was many years before baroclinic models, models without this restriction, produced as good results. This point has now been reached, and present models are able to predict the effect of various influences on the development of cyclones and Rossby waves.

Insofar as these scales of motion are concerned, the computer has become the laboratory of the meteorologist in the truest sense. By altering the parameters in his models, the meteorologist can test the effects of various influences on the atmosphere. The newer models incorporate the effects of solar heating, radiational cooling, formation of clouds and precipitation, as well as the peculiarities of the earth's surface. Much work has been done, but this phase of the science is poised for great advance.

Spectacular changes, based on this work, are taking place in weather forecasting. Large-scale motions are being predicted through the use of electronic computers. Data from the teletype circuits are fed directly to computers which check them for consistency, analyze them for values of the variables at fixed grid points, predict the flow patterns, and draw the synoptic weather map. At the moment, the most success by this method is found in the middle troposphere, but it is only a matter of time till all levels can be accurately forecast by these means.

The mesoscale studies deal with phenomena such as thunderstorms and other small scale circulation systems. This scale of phenomena is also related to very short-range forecasting which is important for certain activities. An example is the forecasting for landing of supersonic aircraft in critical conditions. Such aircraft cannot fly long at low altitudes, and it is essential that the pilot have an accurate forecast for the next twenty to thirty minutes before descending. In the forecasting business, specialists in mesoscale predictions are being developed to work as a team with the specialists in the hemispheric and synoptic scales. This permits a better all-round use of the data. At all levels, the use of the computer will increase as research points the way toward more quantitative methods.

Molecular diffusion is such a slow process that it is of only minor importance in the atmosphere, but diffusion by means of turbulent eddies, eddy diffusion, is a phenomenon of extreme importance to modern man. The statistical description of such diffusive processes has been developed to a high degree. The micro-

meteorologist has become a key figure in man's fight against pollution of the atmosphere and its harmful effects. Besides the obvious pollutants of smoke and noxious gases there is pollution due to the increased use of atomic energy as a source of power. In this sensitive area, an accurate knowledge of the diffusion characteristics of the neighboring region is essential.

One of the great new fields of meteorological research is that of CLOUD PHYSICS. The major tool is the radar, but data are also gathered by other means such as instrumental aircraft and conventional ground instrumentation forming a very fine network. Clouds form when moist air rises, expands and cools. While condensation nuclei are necessary before droplets will form, the atmosphere always has an ample supply of these so that clouds always form when saturation is reached. It has been found also that there is no fixed freezing point for water in the atmosphere and indeed condensation takes place in the liquid state at temperatures substantially below 0°C. The small droplets so formed have proved to be exceedingly stable, and one of the major problems of meteorology has been to learn more of the mechanisms which permit these droplets to grow into large ones. It has long been known that if some droplets freeze, there is the possibility of a distillation from the small droplets to the ice crystals causing the latter to grow. In middle latitudes, this is believed to be the major cause of growth of droplets to raindrop size. There are always a few nuclei in the atmosphere suitable for use as crystallization nuclei, but there are insufficient to cause a large percentage of the droplets to crystallize. Much research has been done to try to improve the richness of the atmosphere with respect to ice nuclei. Silver iodide has proved to be useful, because of its similar structure to that of the ice crystal, and is active at temperatures of about -5°C. Many experiments have been made using silver iodide as a seeding agent to supply additional nuclei to the atmosphere and to increase rainfall. Because of the natural variability of rainfall, it requires a very carefully designed experiment to permit meaningful statistical evaluation of such experiments. Even now it is uncertain that rainfall is actually increased significantly by such techniques except in regions where there is forced uplift of the air as in mountainous areas. Nevertheless, because of the great value that can be attached to even a modest increase in some instances, the commercial cloud-seeding operator has been able to find much business. The other major mechanism for growth of droplets is that of coalescence. This mechanism depends on the production of a few large drops, generally by giant condensation nuclei of hygroscopic salt, which then sweep out swaths of smaller droplets due to differential motion and momentum. This mechanism, important in the tropics, seems to be less amenable to adjustment by man.

Some of the more exciting areas of new knowledge lie in the higher atmosphere. The atmosphere seems to divide naturally into various

layers. The lowest of these is the troposphere where convection rules. The temperature drops off steadily to about 9 or 10 km. The top of this layer is known as the tropopause. The temperature in the lower stratosphere is approximately constant with height but soon begins to increase until it reaches a peak at about 50 km with temperatures comparable to those at the earth's surface. This level is known as the stratopause. The temperature then drops off with height through the mesosphere to about 90 km, a level known as the mesopause.

With increasing amounts of data, what originally seemed to be a rather tranquil picture of the upper atmosphere has undergone some change. We find that the arctic stratosphere generates a rather strong westerly jet stream at about 25 km altitude in wintertime. The winter arctic stratosphere is subject to more or less sharp warmings of substantial magnitude each year in the period between about January and March. This sudden warming marks the end of the stratospheric winter which then changes over to a summer regime. There is also a noticeable 26-month cycle in the tropical stratospheric wind, the direction changing from easterly to westerly about every 26 months. A similar tendency, but much more subdued, has been found at higher latitudes. There is evidence that this cycle affects the stratospheric warmings causing them to develop in Europe first one year and North America the next.

The whole field of services has grown as more knowledge is gained. It is possible here to give only some instances, but it should be realized that this development of widely diversified services based on meteorology is one of the great developments of the last 15 years.

MICHELSON-MORLEY EXPERIMENT

Introduction. The revival and development of the wave theory of light at the beginning of the nineteenth century, principally through the contributions of Young and Fresnel, posed a problem which proved to be of major interest for physics throughout the entire century. The question concerned the nature of the medium in which light is propagated. This medium was called the "aether" and an enormous amount of experimental and theoretical work was expanded in efforts to determine its properties. On the experimental side, a long series of electrical and optical investigations were carried out attempting to measure the motion of the earth through the ether medium. For many years, the experimental precision permitted measurements only to the first power of the ratio of the speed of the earth in its orbit to the speed of light ($v/c \approx 10^{-8}$), and these

"first-order experiments" uniformly gave null results. It became the accepted view that the earth's motion through the ether could not be detected by laboratory experiments of this sensitivity. With the development of Maxwell's electromagnetic theory of light, and especially with its extensions by Lorentz in his electron theory, theoretical explanations for the null results obtained in the early ether drift experiments were provided. These results were in harmony with the Galilean-Newtonian principle of relativity in mechanics, which explains why the essential features of all uniform motions are independent of the frame of reference in which they are observed. In Maxwell's electromagnetic theory, however, the situation was altered when quantities of the second order in (v/c) were considered. According to the Maxwell theory, effects depending on $(v/c)^2$ should have been detectable in optical and electrical experiments. The presence of these "second-order effects" would indicate a preferred reference frame for the phenomena in which the ether would be at rest. At first, this feature of Maxwell's theory implying observable ether drift effects of the second order in (v/c) raised a purely hypothetical question, since the accuracy needed for such experiments was a part in a hundred million, and no experimental techniques then known could attain this sensitivity.

Michelson pondered this problem and it led him to invent the Michelson interferometer, which was capable of measurements of the required sensitivity, and to plan the ether drift experiment which he carried to completion in collaboration with Edward W. Morley at Cleveland in 1887. This famous optical interference experiment was devised to measure the motion of the earth through the ether medium by means of an extremely sensitive comparison of the velocity of light traveling in two mutually perpendicular directions. The experiment, when completed in 1887, gave a most convincing null result and proved to be the culmination of the long nineteenth century search for the ether. At that time, the definitive null result of the Michelson-Morley experiment was a most disconcerting finding for theoretical physics, and indeed for many years repetitions of this experiment and related ones were performed with the hope of finding positive experimental evidence for the earth's motion through the ether. These later experiments, however, have all been shown to be consistent with the original null result obtained by Michelson and Morley. In the years following 1887, their experiment led to extensive and revolutionary developments in theoretical physics, and proved to be a major incentive for the work of FitzGerald, Lorentz, Larmor, Poincaré, and others, leading finally in 1905 to the special theory of relativity of Albert Einstein.

The optical paths in the Michelson-Morley interferometer are shown in plan in Fig. 1. Light from a is divided into two coherent beams at the half-reflecting, half-transmitting rear surface of the optical flat b. These two beams travel at 90° to each other and are multiply reflected by

FIG. 1 Optical paths in the Michelson-Morley interferometer.

two systems of mirrors $d - e$ and $d_1 - e_1$. On returning to b part of the light from $e - d$ is reflected into the telescope at f , and light from $e_1 - d_1$ is also transmitted to f . These two coherent beams of light produce interference fringes. These are formed in white light only when the optical paths in the two arms are exactly equal, a condition produced by moving the mirror at e_1 by a micrometer. c is an optical compensating plate. The effective optical path length of each arm of the

apparatus was increased to 1100 cm by the repeated reflections from the mirror system.

Figure 2 is a perspective drawing of the Michelson-Morley interferometer showing the optical system mounted on a 5 foot square sandstone slab. The slab is supported on the annular wooden float, which in turn fitted into the annular cast-iron trough containing mercury which floated the apparatus. On the outside of this tank can be seen some of the numbers 1 to 16 used to locate the position of the interferometer in azimuth. The trough was mounted on a brick pier which in turn was supported by a special concrete base. The height of the apparatus was such that the telescope was at eye level to permit convenient observation of the fringes when the instrument was rotating in the mercury. While observations were being made, the optical parts were covered with a wooden box to reduce air currents and temperature fluctuations.

This arrangement permitted the interferometer to be continuously rotated in the horizontal plane so that observations of the interference fringes could be made at all azimuths with respect to the earth's orbital velocity through space. When set in motion, the interferometer would rotate slowly (about once in 6 minutes) for hours at a time. No starting and stopping was necessary, and the motion was so slow that accurate readings of fringe positions could easily be made while the apparatus rotated.

The experiment to observe "the relative motion of the earth and the luminiferous ether" for which this instrument was devised, was planned by Michelson and Morley as follows. When the interferometer is oriented as in Fig. 3 with the arm L_1 parallel to the direction of the earth's velocity v in space, the time required for light to

FIG. 2. Michelson-Morley interferometer used at Cleveland in 1887.

FIG. 3. The Michelson-Morley experiment.

travel from M to M₁ and return to M in its new position is,

$$t_1^{(1)} = \frac{L_1}{c-v} + \frac{L_1}{c+v} = \frac{2L_1}{c} \frac{1}{1-\beta^2} \quad \left(\beta = \frac{v}{c} \right)$$

The time for light to make the journey to and from the mirror M₂ in the other interferometer arm L₂ is,

$$t_2^{(1)} = [2L_2(1 + \tan^2 \alpha)^{1/2}] / c$$

and since $\tan^2 \alpha = v^2 / (c^2 - v^2)$

$$t_2^{(1)} = \frac{2L_2}{c} \frac{1}{(1-\beta^2)^{1/2}}$$

When the interferometer is rotated through 90° in the horizontal plane so that the arm L₂ is parallel to *v*, the corresponding times are,

$$t_2^{(2)} = \frac{2L_2}{c} \frac{1}{1-\beta^2}$$

$$t_1^{(2)} = \frac{2L_1}{c} \frac{1}{(1-\beta^2)^{1/2}}$$

Thus, the total phase shift (in time) between the two light beams expected on the ether theory for a rotation of the interferometer through 90° is,

$$\begin{aligned} \Delta t = & \frac{2L_1}{c} \left[\frac{1}{1-\beta^2} - \frac{1}{(1-\beta^2)^{1/2}} \right] \\ & + \frac{2L_2}{c} \left[\frac{1}{1-\beta^2} - \frac{1}{(1-\beta^2)^{1/2}} \right] \\ = & \frac{2(L_1 + L_2)}{c} \left[\frac{1}{1-\beta^2} - \frac{1}{(1-\beta^2)^{1/2}} \right] \end{aligned}$$

For equal interferometer arms, as used in this experiment,

$$L_1 = L_2 = L, \text{ and, since } \beta \ll 1,$$

$$\Delta t \approx \frac{2L}{c} \beta^2$$

The observations give the positions of the fringes, rather than times, so the quantity of

importance for the experiment is the change in optical path in the two arms of the interferometer.

$$\Delta = c \Delta t = 2L(v/c)^2$$

This is the quantity of second order in (*v*/*c*) referred to above.

With the Michelson-Morley interferometer, the magnitude of the expected shift of the white-light interference pattern was 0.4 of a fringe as the instrument was rotated through an angle of 90° in the horizontal plane. Michelson and Morley felt completely confident that fringe shifts of this order of magnitude could be determined with high precision.

In July of 1887, Michelson and Morley were able to make their definitive observations. The experiments which gave their final measurements were conducted at noon and during the evening of the days of July 8, 9, 11, 12 of 1887. Instead of the expected shift of 0.4 of a fringe they found "that if there is any displacement due to the relative motion of the earth and the luminiferous ether, this cannot be much greater than 0.01 of the distance between the fringes."

The result of the Michelson-Morley experiment has always been accepted as definitive and formed an essential base for the long train of theoretical developments that finally culminated in the special theory of relativity. The first important suggestion advanced to explain the null result of Michelson and Morley was G. F. Fitzgerald's hypothesis that the length of the interferometer is contracted in the direction of its motion through the ether by the exact amount necessary to compensate for the increased time needed by the light signal in its to-and-fro path. This contraction hypothesis was made quantitative by H. A. Lorentz in further development of his electron theory in which he introduced the formalism which has since been known as the "Lorentz transformation" for the analysis of relative motions.

H. Poincaré also contributed greatly to both the philosophical and mathematical developments of the theory. As early as 1899, he asserted that the result of Michelson and Morley should be generalized to a doctrine that absolute motion is in principle not detectable by laboratory experiments of any kind. Poincaré further elaborated his ideas in 1900 and in 1904 and gave to his generalization the name "the principle of relativity." He also completed the theory of Lorentz and it was he who named the essential transformation "the Lorentz transformation."

In 1905 Einstein published his famous paper on the "Electrodynamics of Moving Bodies" in which he developed the special theory of relativity from two postulates: (1) the principle of relativity was accepted as the impossibility of detecting uniform motion by laboratory experiments, and (2) the constancy of the speed of light was generalized to a postulate that light is always propagated in empty space with a velocity independent of the motion of the source. Both postulates have a close relationship to the Michelson-Morley experiment, which Einstein knew through

his study of the work of Lorentz. Einstein's paper is generally considered as the definitive exposition of the special relativity principle, and the climax of the century-long developments which had begun with Young and Fresnel to explain the electrical and optical properties of moving bodies. It has since become a major factor in the modern development of both classical and quantum physics.

MICROSCOPE

The word "microscope" comes from a Greek word that means "to view small." Before the microscope could come into existence, the LENS had to be developed. Early knowledge of lenses is very obscure, but we do know that the Chinese porcelain vases had figures on them wearing glasses. These vases date back to 1000 B.C. The Assyrian lens of 700 B.C. was found to be double convex. Sir Austen Henry Layard discovered a plano-convex lens of rock crystal at the Nineveh excavation. The Greeks and Romans wrote about the burning properties of glass lenses as well as the use of glass globules filled with water to aid seeing small objects. Roger Bacon wrote about the magnification power of lenses to aid elderly persons in reading. After his book "Opus Majus" was published in 1266 A.D., nearly two hundred years passed before anything was written discussing advancements in optics. In 1542, the first references about telescopes appeared, and these were written by Nicholas Copernicus of Poland, who discovered that the sun is the center of our universe and that other universes exist.

In Middleburg, Holland, about 1590, the story of the compound microscope begins. Zacharias Janssen developed, by accident, a microscope which was 1 inch in diameter and 6 feet long. This discovery started the parade of inventors and improvers of the microscope, too numerous to mention in their entirety in this article.

Galileo in 1610 introduced a microscope similar to Janssen's but with one major improvement. The Galileo microscope could be focused by means of screw threads on the body and mount. Fontana, Drebbel and Kepler also made microscopes in this early period.

The early microscope lenses had been formed on the end of glass rods by heating and pressing into a given shape. Campani was the first to design and grind lenses which had curves that could be reproduced. Anton van Leeuwenhoek studied all types of specimens under a simple microscope with ground lenses of his own design. He made in excess of 100 microscopes with single lenses, some of which were $\frac{1}{8}$ inch in diameter and had very strong curvature. With these instruments, he discovered bacteria and the existence of corpuscles in the blood.

Robert Hooke, in the last quarter of the 1600's, made a compound microscope that was easy to use. Hooke used a doublet eyepiece from Christian Huyghens to make up the telescope portion (eyepiece) of his compound microscope. The Royal Microscopical Society published Robert Hooke's "Micrographia" in which he describes tissues, blood vessels, textiles, papers, sugars and salt crystals. In about 1750, another Englishman, by the name of John Dollond, improved lenses by devising an achromatic system compounded from both hard and soft glass. In 1759, Dollond succeeded in making an achromatic lens. However, this type of lens was not used in a microscope until 1825. In 1854, the first steps toward standardization of the microscope took place with the "X" designation for magnification based on 250 mm. In 1873, Ernst Abbe from the University of Jena wrote "Theory of Microscope Image Formation" and "Sub-Stage Illumination Apparatus." If the theories discussed in Abbe's book had not been followed, today's microscopes would form very poor, inferior images.

Objective Lenses. The use of simple lenses with high curves for high magnification presents problems that make their use impractical. As the curve of the lens increases, the focal length becomes shorter and more difficult to use. An example of this is the Leeuwenhoek microscope in which one's eye had to be placed on top of the lens in order to see the magnified specimen. A microscope is nothing more than an objective lens magnifying a specimen, the image of which is being viewed by a simple telescope at some convenient distance from the objective lens (Fig. 1).

The aberration of lenses is always a problem to the designers of objectives. The two most common problems are color aberration (chromatic) and distortion of shape aberration (spheric). If a beam of white light passes from a medium of one density into a medium of another density such as air to glass, the beam is bent. As white light is made up of different colors, each wavelength refracts a different amount, and thus we have a spread of the colors called dispersion (Fig. 2). The higher the index of refraction the greater the dispersion. Figures 3 and 4 show the reasons that aberrations appear in lenses. A simple, and many times the most economical, practical way to correct spherical aberration is to place a diaphragm in front of the lens so as to cut off the thin edges which bend the light more (Fig. 4 and 5). To correct chromatic aberrations various types of glass must be selected for index of refraction and dispersion; they should then be combined to have as many colors as possible come to focus at the same point.

The objective is the most important single factor of the microscope, for through its power to resolve minute structure, we see small objects crisp and clear. Magnification, although it is of secondary importance to the resolving power of the objective, is absolutely essential. In order to have high resolution, a lens must be the best possible compromise on the correction of the

FIG. 1. Compound microscope showing optics and image position.

FIG. 2. Bending illustrates refraction; spreading illustrates dispersion.

various aberrations such as spherical, coma, and chromatic. The matter of resolution in actual practice is based not only on the correction of the lenses, but on the ability of the user to use the proper objective, ocular, condenser, and illumination, and on controlling the aperture diaphragm and field diaphragms to their optimum settings for the system being used. It is not always possible to achieve the resolutions of a given lens even after proper manipulation because the detail is obscured by the background and the surrounding parts of the specimen. Technique in preparing the material being studied is of the utmost importance. Proper staining, thickness and mounting also determine how much we will resolve.

Resolution, angular aperture and wavelength of light being used are related. The angle of the cone of light is dependent on the refractive index of the medium between the objective front lens and the glass cover slip over the specimen (Fig. 6). Present-day objectives have clearly marked on their mounts the relationship between the angular cone and refractive index of the working medium, expressed in terms of numerical aperture (*N.A.*)

$$N.A. = i \sin \theta$$

where θ is one-half the angle of the cone of light entering the objective and i is the refractive index of the medium in which the objective is working. From this formula theoretically one

FIG. 3. Chromatic aberration.

FIG. 4. Spherical aberration.

FIG. 5.

FIG. 6.

can see that the *N.A.* in air can never be greater than 1 because *i* would represent air with a refractive index of 1.

The relationship of *N.A.* and resolving power is as follows:

$$R = N.A. / \lambda$$

where λ is wavelength of light and *R* is the number of lines being separated by the lens.

There are three main classes of objectives: achromatic, fluorite, and apochromatic; the achromats are corrected for two colors (red and green) chromatically and one color spherically. To obtain more correction, substitution of the sandless glasses such as fluorite gives a little better correction than the achromats. The apochromatic objectives produce the best images, those finest in color correction and clarity. Apochromatic objectives are corrected for three colors chromatically and two spherically. To achieve the added value in the apochromatic objectives, they must utilize compensating eyepieces to correct for the color spread and a corrected condenser of a numerical aperture equal to or greater than the objective numerical aperture.

When using the microscope, it is very important to consider the working distance, depth of field and coverglass thickness. The working distance is the amount of free space from the front of the objective to the coverglass, and as the power and the *N.A.* increase, the working distance becomes shorter. Therefore, when a counting chamber with its normal coverglass is used, magnifications up to about 45X and *N.A.*'s up to about .66 can be used to view specimens. Objectives of higher magnification and larger *N.A.*'s reduce the working distance sufficiently to cause breakage of cover slips or inability to focus sharply on the specimen.

Depth of focus is the amount of thickness of the specimen that is in focus at one time. This amount decreases as magnification and *N.A.*

increase. In photomicrography this is very important and the specimen must be thin enough or parts of the specimen will be out of focus, obscuring detail of the portion that is in sharp focus. High-power dry objectives with correction collars to compensate for coverglass thickness should be used with cover glasses other than .18 mm to have optimum correction for spherical aberration. Objectives without the coverglass correction collar are designed and optically corrected for the use of coverglasses of .18 mm thickness. Coverglasses of other thickness increase the aberration, especially when using the high dry objectives.

Eyepieces. The eyepiece acts as the telescope of the system merely to remagnify the primary image of the objective; thus eyepiece magnification adds nothing to the resolution of the system. The practical rule is that one should not normally magnify more than 1000X the *N.A.* of the objective. More magnification is normally called empty magnification. However, in some instances to aid in counting, measuring, or drawing, ease of use can be achieved by using a higher-power eyepiece. Many companies are now making eyepieces with high eye relief so that persons requiring the additional distance between the eye lens and the Ramsden circle of the eyepiece can continue to wear their glasses while using the microscope.

There are many types of eyepieces. Four of the most common are Huygenian, periplane, widefield and compensating. The Huygenian is by far the simplest in design having 2 elements and being the least corrected, but most commonly, used eyepiece. Periplane eyepieces have greater correction thus producing better images as to color and flatness, while having about the same field of view as the Huygenian. Compensating eyepieces were designed for use with the apochromatic objectives to compensate for the objective deficiencies. In recent years the need to view more has brought about the development of eyepieces which cover greater fields of view.

Condensers. The condenser is commonly the most misused part of the microscope. A condenser has one optimum setting as to height and aperture diaphragm setting which controls the *N.A.* for each objective. The condenser height and aperture diaphragm should not be used to control the intensity of the illumination. If the aperture diaphragm is opened too far, the specimen is flooded with light and detail is washed out. If closed too far, the *N.A.* and detail are lost and diffraction becomes quite apparent.

Illuminators. The illuminator is a very essential part of the microscope. If one is to achieve the maximum from the microscope in terms of resolution, clarity and ease on the eyes of the user, a good illuminator must be employed. An illuminator must have a condensing system large enough to accommodate the apertures of the microscope and an iris diaphragm, sometimes referred to as a field stop. The condensing system and field stop must be focusable. To achieve the ultimate in illumination, filters and adjustable

mirrors in the illuminator help to adjust for maximum light through the system.

In the early days of microscopy, critical illumination was used by most microscopists. The source of light was broad such as the sun, reflection of the sun on white clouds or oil wick lamps. The source was focused so it would appear in the field of view (Fig. 7). Of course, the disadvantages of this system were size of the source

FIG. 7. Critical illumination.

and unevenness of illumination. The introduction of the concentrated coil filament lamps made use of critical illumination impractical due to the fact that the coil source was small and did not fill the aperture. Kohler solved this problem and the system is named after him. In Kohler illumination, the filament of the lamp is focused on the condenser iris (often called the aperture stop), and the field iris is focused so it will be in focus at the same plane as the specimen viewed through the microscope (Fig. 8).

FIG. 8. Kohler illumination.

The use of filters makes it possible to change the visual appearance of the specimen. The use of a green filter for black and white photomicrography will, in many cases, increase the contrast and produce an excellent photograph.

The proper way to control the intensity of

illumination is to use neutral density filters. These filters control the intensity without changing the color balance of the source, e.g., if the source emits 20 per cent blue, 50 per cent green and 30 per cent red without a filter, then when a 50 per cent filter is placed in the system, only 50 per cent of the original light comes through the filter, but this 50 per cent is still composed of 20 per cent blue, 50 per cent green and 30 per cent red. We have cut down only the total intensity, not the balance.

Types of Microscope. There are many types of microscopes. Basically they are all similar, i.e., they have one or more objectives, eyepieces, condensers and some mechanical means to focus and manipulate the specimens. Often, in order to change from one type of microscope to another, only accessories have to be added.

The phase contrast method of microscopy was introduced in 1935 by Professor F. Zernike. Phase contrast is most useful in research and industry where an approach, other than the normal one, is necessary. The main advantage lies in the fact that contrast can be greatly enhanced in living and or unstained material, where, normally, little or no contrast exists with a bright field microscope. Direct observation of living material, such as yeast, bacteria and fungi, has made possible rapid, positive identification of specific organisms as well as observation of phenomena within the cells that have gone unnoticed for many years. Phase contrast relies on the combining of light waves and is dependent on amplitude and phase of these waves.

Dark field microscopy consists of a condenser with an opaque central stop which will not allow any direct light to enter the objectives. The circular cone of light is focused on the specimen which becomes very bright on a black background. Dark field shows objects that are too small to be seen by the bright field microscope, it is often used in the identification of spirochaetes, colloidal materials and chemical bonding.

Polarizing microscopes, in addition to having the normal components, have a polarizer and an analyzer. The light enters the polarizer where it is forced to vibrate in one direction. The light then passes through the condenser and objective to the analyzer which is set with the direction of vibration 90° to the polarizer; consequently no light is allowed to pass to the eyepiece. When material is placed in the system at the specimen plane, the material, in many cases, rotates the plane of polarization. Now that the polarized light has been rotated, a portion will pass through the eyepiece and be observed. Crystals that rotate the plane of polarization become either colored or white on a dark background. Crystals are classified by the way that they look under polarized light and by the amount of rotation which differs for each crystal. Other properties of crystals that can be studied by the polarizing microscopes are optical sign, extinction angle, birefringence, refractive index and pleochroism (see POLARIZED LIGHT).

The stereoscopic microscope is basically two microscopes, one for each eye. These two microscopes are mounted conveniently in a single housing for easy use. Each eye views the same specimen from a different angle producing a stereoscopic, three-dimensional view. The view through this type of microscope gives the user greater depth, erect image and larger fields than with the compound microscope. These instruments are used in dissection, genetic studies, and the assembly of small parts.

There are many universities, companies and individuals that have advanced the microscope to its present form. It is certainly one of the most important factors in our knowledge of bacteria and other medical sciences. Industry, in its quest for quality today, is investigating more closely the minute workings of its products, and with the advent of space exploration, the need for miniaturization has emphasized the part the microscope can play in studying, understanding and manipulating specimens.

MICROWAVE SPECTROSCOPY

Microwaves are electromagnetic waves which range in length from about 30 cm to a fraction of a millimeter or in frequency from 10^9 to 0.5×10^{12} cps. This corresponds to the rotational frequency range of a large class of molecules. Thus, microwave radiation passing through a gas can be absorbed when the rotating electric dipole moment of the molecule interacts with the electric vector of the radiation. Likewise, absorption can take place if the rotating magnetic moment of the molecule interacts with the magnetic vector of the radiation.

Most microwave spectroscopy is based on a study of transitions induced by interaction of the molecular electric dipole with the incident radiation.

A microwave spectrometer then consists basically of a monochromatic microwave source (klystron), an absorption cell, and a detector. The

absorption cell must transmit the microwave of interest and in the centimeter region may have cross-sectional dimensions of 1×4 cm and may be a few meters in length. Normally a metal strip is inserted along the length of the cell and is insulated from the cell. In this way, an auxiliary, spatially uniform electric field may be established in the absorption cell without affecting the microwaves. The Stark effect thereby produced splits the molecular energy levels into a series of levels and enables one to identify the transition.

The Hamiltonian for a rotating rigid asymmetric molecule including possible fine and hyperfine structure terms is given in Eq. (1). It is assumed, as is most commonly so, that the molecule is in a $^1\Sigma$ state, i.e., that there is no net electronic angular momentum and no net electron spin (singlet state). The Hamiltonian written is quite general and in many cases not all of the terms shown in Eq. (1) need be included to account for spectra observed under normal resolution.

A brief description will be given of each term in order that one may most simply understand the kinds of interactions which may occur and which may be pertinent to an understanding of the spectra of rotating molecules.

$$H = H_R + H_{\text{dist.}} + H_S + H_{\text{Ze}} + H_Q + H_{\text{Ze}} + H_D \quad (1)$$

1. H_R is the framework rotational kinetic energy and may be written

$$H_R = \frac{\hbar^2}{8\pi^2} \left[\frac{J_a^2}{I_a} + \frac{J_b^2}{I_b} + \frac{J_c^2}{I_c} \right]$$

where J_a , J_b , and J_c are the components of the total angular momentum in units of \hbar referred to body-fixed principal axes. I_a , I_b , and I_c are the moments of inertia about the respective principal axes. The Hamiltonian may be written

$$H_R = AJ_a^2 + BJ_b^2 + CJ_c^2$$

or displaying the total angular momentum J

$$H_R = AJ^2 + (B - A)J_b^2 + (C - A)J_c^2$$

A , B and C are rotational constants with $A > B > C$. In this form, units can be chosen so as to give energy levels directly in megacycles per second. H_R describes a rigid symmetric top if I_a is equal to I_b . For a diatomic molecule, $I_a = I_b$ and $I_c \gg 0$. ($1/I_c$ becomes very large, and the rotational levels about the c axis are too far apart to become excited by microwaves). For the spherical rotor, $I_a = I_b = I_c$, but this implies no dipole moment and therefore no observable rotational spectrum.

Energy levels for the symmetric top may be determined by analytical methods,¹ by factorization method², or by using the commutation properties of the angular momenta.³ In Eulerian coordinates, the wave equation separates, and the wave function has the form

$$\psi_J = N(JKM)e^{iK\phi}e^{iM\psi}\Theta_{JKM}(\theta)$$

Where Θ_{JKM} is the solution to the differential

equation in the polar angle θ which results after separation of the simple terms in the azimuthal angle ϕ and the angle ψ which defines the direction of the line of nodes. The equation for Θ_{JKM} with appropriate change of variable becomes the equation for the Jacobi polynomials.

The solution ψ is characterized by three quantum numbers: J , the total angular momentum; K the component of angular momentum along the symmetry axis of the molecule; and M , the magnetic quantum number or projection of J along an arbitrary space axis. The energy does not depend on M in the absence of external electric or magnetic fields. The energy levels for the symmetric top have the form

$$E_{J,K} = BJ(J+1) + (C-B)K^2$$

The rotational constants $A \approx B$ and C may typically range from 2000 to 300 000 Mc for presently observable spectra.

Selection Rules. In all but the accidentally symmetric top, the permanent dipole will be along the symmetry axis. In this case, the selection rules for absorption of radiation through rotation are:¹

$$J \rightarrow J \pm 1, K \rightarrow K$$

For a component of the dipole moment perpendicular to the symmetry axis, the selection rules are

$$\Delta J = \pm 1, 0 \text{ and } \Delta K = \pm 1$$

In both cases, $\Delta M = \pm 1, 0$.

The wave functions for the asymmetric top are expressed as linear combinations of symmetric top functions. The energy remains diagonal in J but not in K . One must, therefore, arbitrarily label the energy levels and determine the selection rules. This will not be done here. In order to do this, however, one needs to know only the nonvanishing matrix elements of the three components of the dipole moment for the symmetric top given above.

The selection rule for diatomic molecules is simply $J \rightarrow J \pm 1, M \rightarrow M, M \pm 1$.

2. $H_{\text{dist.}}$ describes centrifugal stretching corrections to the energy levels which for an asymmetric molecule can be quite complicated. Corrections for a symmetric top molecule are easily derived, and the framework energy in this case including centrifugal stretching is given by:

$$E_{J,K} = BJ(J+1) + (C-B)K^2 - D_J J^2(J+1)^2 - D_{JK} J(J+1)K^2 - D_K K^4$$

For a non-rigid diatomic molecule or linear polyatomic molecule, $K = 0$, and the energy is given by:

$$E_J = B_v J(J+1) - D_v J^2(J+1)^2$$

and since $J \rightarrow J+1$, for absorption the line frequencies are:

$$\nu_r = 2B_v(J+1) - 4D_v(J+1)^3$$

where B_v is the "effective" spectral constant,

$h/(8\pi^2 I_v)$, for the particular vibrational state for which the rotational spectrum is observed, and where D_v is the centrifugal stretching constant for that state.

In terms of the constants B_e and D_e for the hypothetical vibrationless state, B_v and D_v for diatomic molecules are:

$$B_v = B_e - \alpha(v + \frac{1}{2})$$

$$D_v = D_e + \beta(v + \frac{1}{2})$$

where α and β are interaction constants which are very small in comparison with B and D , respectively, and where v is the vibrational quantum number. For linear polyatomic molecules, there is more than one vibrational mode, and the above equations must be written in the more general form

$$B_v = B_e + \sum_i \alpha_i \left(v_i + \frac{d_i}{2} \right)$$

$$D_v = D_e + \sum_i \beta_i \left(v_i + \frac{d_i}{2} \right)$$

where the summation is taken over all the fundamental modes of vibrations. The subscript i refers to the i th mode, and d_i represents the degeneracy of that mode.

In the analysis of spectra, the variations of the stretching constants D_J and D_{JK} with vibrational state are customarily neglected. It is seldom possible to obtain sufficient data for the evaluation of these effects upon B and for determination of B_e even for the simpler symmetric tops.

Centrifugal stretching constants may typically range from 8.5 to 0.002 Mc or less.⁵

3. The third term H_S is the contribution to the Hamiltonian arising from the Stark effect and may be written as

$$H_S = \mu_e \cdot \mathcal{E}$$

where μ_e is the vector dipole moment and \mathcal{E} is the external electric field.

If the dipole moment lies along the "c" body-fixed principal axis, H_S has the form

$$H_S = \mu_e (A_x^c \mathcal{E}_x + A_y^c \mathcal{E}_y + A_z^c \mathcal{E}_z)$$

where A_x^c, A_y^c, A_z^c are the direction cosines of the c principal axis with space-fixed axes xyz. $\mathcal{E}_x, \mathcal{E}_y$, and \mathcal{E}_z are the components of the electric field along the space-fixed axes. Additional terms will be added to this expression if the dipole moment has components along the remaining two principal axes. In order to obtain the contribution to the energy from this part of the Hamiltonian, one must evaluate matrix elements of the direction cosines with respect to symmetric top wave functions. Methods described in reference 3 enable one to do this.

In the case of a symmetric top, the dipole moment will have a component only along the c axis so that H_S consists of the single term $A_x^c \mathcal{E}_x$ when $\mathcal{E}_x = \mathcal{E}_y = 0$.

In this case, the energy associated with H_S is

diagonal in all three quantum numbers JKM and has the form

$$E_s = -\mathcal{E}_z \mu_e \frac{MK}{J(J+1)}$$

where M , the "magnetic quantum number," measures the component of J along \mathcal{E}_z and can take the values $M = J, J-1, \dots, -J$. The selection rules for M are $M \rightarrow M$; $M \rightarrow M \pm 1$, depending on the polarization of the microwaves.

For asymmetric molecules, μ_e will in general have components along the A and B axes as well as C . The A and B components give rise to matrix elements off diagonal in J , K and M . For a dipole moment of 1 debye and an electric field of 1 volt/cm, $\mu_e \mathcal{E}$ is 0.5 Mc.

4. H_{ze} is the contribution to the Hamiltonian due to the interaction of the external magnetic field with the magnetic moment which is created by rotation of the molecule.

We also include the interaction of the external magnetic field with the dipole moment of individual nuclei. For a molecule with two nuclear spins, I_1 and I_2 , this may be written

$$H_{zi} = \sum_{j,k} \mu_n(J)_{jk} J_{jk} + \mu_n g_1 (I_1 \cdot H) + \mu_n g_2 (I_2 \cdot H)$$

where $g(J)$ is in general a tensor, J_j are components of J along axes to which H is referred, H_k are the components of the field H usually referred to the space-fixed axes, and g_1 and g_2 are called the nuclear magnetic g factors. The interaction between J and H is the same order as that between the nuclear spin and H . Therefore, we introduce the term μ_n so that g coefficients are of the order of unity. Thus for a field of one gauss, the quantity $\mu_n g H$ is 0.7 kc.

For molecules with electronic angular momentum, μ_n in the first term is replaced by μ_0 , the Bohr magneton which is 1836 times larger than μ_n . Thus, in this case $\mu_n g H$ is ~ 1.4 Mc for a field of one gauss.

5. H_Q is the energy of interaction of the nuclear electric quadrupole with the gradient of the electric field produced by the electrons in the molecule at nucleus with spin I . For a nucleus on the axis of a symmetric top, the quadrupole operator is ordinarily considered to be of the form:

$$H_Q = \frac{-eQq}{2J(2I-1)(2J-1)(2J+3)} \left\{ 1 - \frac{3K^2}{J(J+1)} \right\} \left[3(J+1)^2 + \frac{3}{2}(J \cdot I) - J^2 I^2 \right]$$

This operator yields only those matrix elements of the quadrupole interaction which are diagonal in J . The diagonal contributions are sufficient for most cases.

In the expression above, eQ is defined by

$$eQ = (I, I | \int \rho_n [3z_n^2 - r_n^2] d\tau_n | I, I)$$

where ρ_n is the nuclear charge density at a distance r_n from the center of charge of the nucleus and $d\tau$ is the differential volume element for the

nuclear volume. z_n is the position coordinate along the direction of the nuclear spin I . The matrix element considered is that for which $M_I = I$.

The quantity q is defined as

$$q = \left[\frac{\partial^2 V}{\partial c^2} \right]_{(r_n \rightarrow 0)}$$

where V is the electrostatic potential due to the electronic cloud and other nuclei surrounding the nucleus and c is the axis in the body-fixed system which is parallel to the symmetry axis of the molecule. The quantity eqQ varies from ~ 1000 to 1000Mc/sec although the intermediate values are more common.⁵

6. H_{zi} represents the interaction between the magnetic field caused by rotation of the charged particles which make up the molecule and the nuclear magnetic moments of the nuclei. For the case of 2 nuclei, this takes the form

$$H_{zi} = \sum_{j,k} C(1)_{jk} J_{jk} I_{1k} + \sum_{j,k} C(2)_{jk} J_{jk} I_{2k}$$

$C(1)$ and $C(2)$ represent the internal magnetic moment tensors for the two nuclei. The C coefficients are of the order of 10^{-2}Mc^2 . J and I are pure numbers. This correction will therefore be unimportant for the large majority of molecules.

7. H_D is the dipole interaction between the two nuclei which may be written in the form

$$H_D = \frac{g_1 g_2 \mu_n^2}{R^3} \left[I_1 \cdot I_2 - \frac{3(I_1 \cdot R)(I_2 \cdot R)}{R^2} \right]$$

where g_1 and g_2 are the nuclear gyromagnetic ratios of the nuclei, μ_n is the nuclear magneton and R is the distance between the two nuclei.

The operator which is usually used to represent this interaction is

$$H_D = \frac{g_1 g_2 \mu_n^2}{R^3} \frac{[3(I_1 \cdot J)(I_2 \cdot J) + 3(I_2 \cdot J)(I \cdot J - 2)I_1 \cdot I_2 J^2]}{(2J-1)(2J+3)}$$

This operator, like that given for the quadrupole interaction above, and usually quoted in the literature, will yield only those matrix elements which are diagonal in the quantum number J . The coefficient $g_1 g_2 \mu_n^2 / R^3$ may be of the order of a kilocycle. This correction is observed only in very rare cases.⁷

Matrix elements for all of the above-mentioned components of the Hamiltonian may be evaluated by the methods in references 6. The matrix elements themselves are too lengthy to be tabulated here.

There is an additional interaction which, for completeness should be mentioned. The nuclear spins may interact with one another through mutual coupling with the surrounding electron cloud. This gives a correction of the form $C I_1 \cdot I_2$. The coefficient C may be larger than that in the dipole-dipole interaction term.

The preceding discussion emphasizes the measurement and interpretation of microwave absorption spectra. One is thereby led to a knowledge of the structure of the molecule, the value of nuclear spins, and various coupling constants.

Microwave spectroscopy is also an effective technique for determination of barrier heights associated with internal rotation.^{8,9,10}

A discussion of line shapes and intensities has been omitted. We have not discussed electronic magnetic resonance, that is, absorption associated with a net nonzero electron spin. Absorptions of this type are observed in molecules, free atoms, radicals, and solids.

For further details and a discussion of topics omitted, the reader is referred to the excellent article of W. Gordy⁸ and the text⁵ by Townes and Schalow on microwave spectroscopy.

MICROWAVE TRANSMISSION

That portion of the electromagnetic spectrum which lies adjacent to the far-infrared region is commonly identified by the term microwaves. The shortest and longest practical microwave wavelengths are in the vicinity of 1 mm (3×10^{11} cps or 3×10^5 mc/sec, abbreviated 300 000 Mc or 300 gc) and 10 cm (3×10^9 cps, abbreviated 3000 Mc or 3 Gc), respectively.

The development of microwave transmission on a large scale began in 1940 with the advent of the magnetron, an electronic generator of high-power microwaves. The magnetron made possible

wartime radar at approximately 3000 Mc and led to the utilization of waveguides for the efficient transmission of microwaves from the generator to the transmitting antenna and from the receiving antenna to the detector.

In essence, a waveguide is a hollow metal tube capable of propagating electromagnetic waves within its interior from its sending end to its receiving end. Unlike waves in space which propagate outward in all directions, waves in waveguides are fully confined while they propagate. By far, the most commonly used waveguide is rectangular in cross section. Such rectangular waveguides have the property of maintaining wave polarization over wide frequency ranges.

Propagation in a waveguide is limited by the cross-section dimensions of the guide. In a rectangular guide, the highest wavelength that can be propagated is equivalent to twice its width. For example, to transmit a 3000-Mc signal in a rectangular waveguide, the width of the guide must be at least 5 cm. At 300 Mc, this width becomes 50 cm. Thus, for the transmission of microwaves, waveguides are reasonable in size. Furthermore, when used with ferrites and magnets, waveguide components can be designed to function as isolators, circulators, modulators, discriminators, or attenuators.

The propagation of radio signals in space between transmitting and receiving antennas can be described in terms of ground waves, sky waves and space waves. At microwave frequencies, ground waves attenuate completely within a few feet of travel, sky waves are influenced by the ionosphere and can penetrate through into outer space, and space waves behave like light waves as they travel through the atmosphere immediately above the surface of the earth. Microwave space waves travel in a direct line of sight, can be reflected from smooth conducting surfaces, and can be focused by reflectors or lenses. Their behavior is similar to light waves and they follow many of the rules of optics.

If a space wave is radiated from a point antenna, the radiated energy spreads out like an ever-expanding sphere, and the amount of energy per square foot of wave front decreases inversely with the square of the distance from the antenna. The power that can be extracted from a wave front by a similar point antenna varies inversely with the square of the frequency. Thus, a point antenna receives power which is inversely proportional to both the square of the distance from the source and the square of the frequency. The ratio of the power received to the total power radiated is known as path attenuation.

When the receiving antenna is a parabola-shaped dish, the power extracted from the wave front is greatly increased. The ratio of the power received by such an antenna to the power received by a theoretical point antenna is defined as antenna gain. The gain of a parabolic antenna increases with the antenna area and the operating frequency. Thus, for a given microwave path with fixed-size antennas, the path attenuation increases with frequency, the antenna gain increases with

frequency, and the over-all result is that one tends to offset the other.

In broadcast radio, signal power radiates equally in all directions and a receiving antenna picks up only a tiny fraction of the signal power. To overcome this low efficiency, the broadcast station must transmit a large amount of power. By contrast, a point-to-point microwave system radiates only a small amount of power, but it uses a directional transmitting antenna to concentrate power into a narrow beam directed toward the receiving antenna. Consequently, such systems are characterized by high efficiencies.

Because microwave transmission follows essentially a straight line, the distance between terminals tends to be limited by the curvature of the earth and by obstructions such as trees, buildings and mountains. Reflectors are often used to redirect a beam over or around an obstruction. The simplest and most common reflector system consists of a parabolic antenna mounted at ground level which focuses a beam on a reflector mounted at the top of a tower. This reflector inclined at 45° redirects the beam horizontally to a distant site where a similar "periscope" reflector system may be used to reflect the beam down to another ground level.

Often a tower cannot provide clearance over an obstruction. For example, if two sites are separated by a mountain, it may be necessary to use a large, flat surface reflector referred to as a "billboard" reflector. In a typical system, a "billboard" reflector might be located at a turn in a valley, effectively bending the beam to follow the valley. Many arrangements are possible which, in effect, resemble huge mirror systems.

Microwaves are ideally suited for communication systems where a broad frequency bandwidth of the order of several megacycles is required for the rapid transmission of signals which contain a large amount of information, such as in television. Most of the major cities of the United States are serviced by microwave television links so that they can receive television programs which originate from other cities. These systems can also accommodate thousands of telephone channels.

In 1960, experiments were initiated which aimed toward communicating over transoceanic distances via microwaves by utilizing orbiting balloons as reflectors. Echo I and Echo II were attempts in this direction.

Microwaves are broadly used for radar, navigation, and for the launching, guidance, and fusing of missiles. A typical defense project which uses microwave techniques is the DEW radar line which protects the United States from external enemy attacks.

Of recent vintage, is the U.S. Air Force's HAYSTACK facility being built at Millstone Hill in Massachusetts for spacecraft tracking, space communications, and radar astronomy. This facility is expected to track a target the size of a dime at a distance of 1000 miles. It will be the first western radar capable of making contact with more distant planets, such as Mars, Mercury

and Jupiter. It will operate at a microwave frequency of 27 500 Mc.

MODULATION

Modulation is defined as the process, or the result of the process, whereby some characteristic of one wave is varied in accordance with some characteristic of another wave (ASA). Usually one of these waves is considered to be a carrier wave while the other is a modulating signal. The various types of modulation, such as amplitude, frequency, phase, pulse width, pulse time, and so on are designated in accordance with the parameter of the carrier which is being varied.

Amplitude modulation (AM) is easily accomplished and widely used. Inspection of Fig. 1 shows that the voltage of the amplitude modulated wave may be expressed by the following equation

$$v = V_c(1 + M \sin \omega_m t) \sin \omega_c t$$

where ω_c and ω_m are the radian frequencies of the carrier and modulating signals, respectively. The modulation index M may have values from zero to one. When the trigonometric identity $\sin a \sin b = \frac{1}{2} \cos(a-b) - \frac{1}{2} \cos(a+b)$ is used in the equation above, this equation becomes

$$v = V_c \sin \omega_c t + \frac{MV_c}{2} \cos(\omega_c - \omega_m)t - \frac{MV_c}{2} \cos(\omega_c + \omega_m)t$$

This equation shows that new frequencies, called side frequencies or side bands, are generated by the amplitude modulation process. These new frequencies are the sum and difference of the carrier and modulating frequencies.

Amplitude modulation is accomplished by mixing the carrier and modulating signals in a nonlinear device such as a vacuum tube or transistor amplifier operated in a nonlinear region of its characteristics. The nonlinear characteristic produces the new side-band frequencies. Frequency converters or translators and AM detectors are basically modulators. The various types of pulse modulation are actually special types of amplitude modulation.

Frequency modulation (FM) is illustrated by Fig. 2. The frequency variation, or deviation, is

FIG. 1. Amplitude modulation.

FIG. 2. Frequency modulation.

proportional to the amplitude of the modulating signal. The voltage equation for a frequency modulated wave follows.

$$v = V_c \sin(\omega_c t + M_f \sin \omega_m t)$$

The modulation index M_f is the ratio of maximum carrier frequency deviation to the modulating frequency. This ratio is known as the deviation ratio and may vary from zero to values of the order of 1000. FM requires a broader transmission bandwidth than AM but may have superior noise and interference rejection capabilities. A large value of modulation index provides excellent interference rejection capability but requires a comparatively large bandwidth. The approximate bandwidth requirement for a frequency modulated wave may be obtained from the following relationship

$$\text{Bandwidth} = 2 (\text{Modulating frequency}) (M_f + 1)$$

The noise and interference characteristics of FM transmission are normally considered satisfactory when the modulation index or deviation ratio is five or greater.

Phase modulation is accomplished when the relative phase of the carrier is varied in accordance with the amplitude of the modulating signal. Since frequency is the time rate of change of phase, frequency modulation occurs when the phase modulating technique is used and vice versa. In fact, the equation given for a frequency-modulated wave is equally applicable for a phase-modulated wave. However, the phase-modulating technique results in a deviation ratio, or modulation index, which is independent of the modulating frequency, while the frequency modulating technique results in a deviation ratio which is inversely

proportional to the modulating frequency, assuming invariant modulating voltage amplitude in each case.

The phase-modulating technique can be used to produce frequency-modulated waves, providing the amplitude of the modulating voltage is inversely proportional to the modulating frequency. This inverse relationship can be obtained by including, in the modulator, a circuit which has a voltage transfer ratio inversely proportional to the frequency.

MOLE CONCEPT

The mole (derived from the Latin *mole* - heap or pile) is the chemist's measure of amount of pure substance. It is relevant to recognize that the familiar *molecule* is a diminutive (little mole). Formerly, the connotation of *mole* was a "gram molecular weight." Current usage tends more to use the term *mole* to mean an amount containing Avogadro's number of whatever units are being considered. Thus, we can have a mole of atoms, ions, radicals, electrons or quanta. This usage makes unnecessary such terms as "gram-atom," "gram-formula weight," etc.

A definition of the term is: *The mole is the amount of (pure) substance containing the same number of chemical units as there are atoms in exactly twelve grams of C^{12} .* This definition involves the acceptance of two dictates—the scale of atomic masses and the magnitude of the gram. Both have been established by international agreement. Usage sometimes indicates a different mass unit, e.g., a “pound mole” or even a “ton mole”; substitution of “pound” or “ton” for “gram” in the above definition is implied.

All stoichiometry essentially is based on the evaluation of the number of moles of substance. The most common involves the measurement of mass. Thus 25.000 grams of H_2O will contain 25.000/18.015 moles of H_2O ; 25.000 grams of sodium will contain 25.000/22.990 moles of Na (atomic and formula weights used to five significant figures). The convenient measurements on gases are pressure, volume and temperature. Use of the ideal gas law constant R allows direct calculation of the number of moles $n = (P \cdot V)/(R \cdot T)$. T is the absolute temperature; R must be chosen in units appropriate for P , V and T (e.g. $R = 0.0820$ liter atm mole $^{-1}$ deg K^{-1}). It may be noted that acceptance of Avogadro's principle (equal volumes of gases under identical conditions contain equal numbers of molecules) is inherent in this calculation. So too are the approximations of the ideal gas law. Refined calculations can be made by using more correct equations of state.

Many chemical reactions are most conveniently carried out or measured in solution (e.g., by titration). The usual concentration convention is the *molar* solution. (Some chemists prefer to use the equivalent term *formal*). A 1.0 molar solution is one which contains one mole of solute per liter of solution. Thus the number of moles of solute in a sample will be

$$n = \text{Volume (liters)} \cdot \text{Molarity (moles liter)}$$

The amount of chemical reaction occurring at an electrode during an electrolysis can be expressed in moles simply as $n = q/(z \cdot \mathcal{F})$ where z is the oxidation number (charge) of the ion and \mathcal{F} is the faraday constant, 96 487.0 coulombs/mole. Thus the *faraday* can be considered to be the charge on a mole of electrons. This affords one of the most accurate methods of evaluating the avogadro number ($6.02252 \cdot 10^{23}$), since the value of the elementary charge is known with high precision.

Modern chemistry increasingly uses data at the atomic level for calculation at the molar level. Since the former often are expressed as quanta, appropriate conversion factors must involve the avogadro number. Thus the *einstein* of energy is that associated with a mole of quanta, or $E = Nh\nu$. Thus light of 2537 Å wavelength will represent energy of

Another convenient conversion factor is 1 eV/particle = 23.05 kcal/mole.

The chemist's use of formulas and equations always implies reactions of moles of material, thus $HCl(g)$ stands for one mole of hydrogen chloride in the gaseous state. Thermodynamic quantities are symbolized by capital letters standing for molar quantities, e.g., C_p (heat capacity at constant volume in cal mole $^{-1}$ deg $^{-1}$), G (Gibbs function in cal/mole), etc. At times it is more convenient to convert an extensive property into an intensive expression. This is especially true in dealing with multicomponent systems. These are referred to as “partial molal quantities” and are given a symbol employing a bar over the letter. Thus the partial molal volume, \bar{V}_1 ($\partial V/\partial n_1$) is the rate of change of the total volume of a solution with the amount (number of moles) of component 1.

MOLECULAR WEIGHT

The molecular weight of a chemical compound is the sum of the atomic weights of its constituent atoms. The molecule is the smallest weight of a substance which still retains all of its chemical properties. By convention, each atomic weight, and therefore molecular weights, are expressed relative to the arbitrary value, 16, for the oxygen atom. For example, the molecule of acetic acid, CH_3COOH , contains two atoms of carbon, four of hydrogen, and two of oxygen, so that its molecular weight is the sum of $2(12.01) + 4(1.01) + 2(16.00)$, which totals 60.06. This molecular weight value is clearly in arbitrary units, but a related quantity, the gram-molecular weight or mole, is the molecular weight expressed in grams. One mole of any compound has been found to contain $6.023 \cdot 10^{23}$ molecules, and this number is called the avogadro constant.

The most commonly used system of molecular weights, called “chemical,” is based on the value 16.00 for the naturally occurring mixture of isotopes of oxygen. For purposes where single molecules are to be compared, another system of “physical” molecular weights is sometimes used. This is based on the value 16.00 for

$$E = \frac{6.023 \cdot 10^{23}(\text{quanta/mole}) \cdot 6.62 \cdot 10^{-27}(\text{erg-sec}) \cdot 3.000 \cdot 10^{10}(\text{sec/cm})}{2.537 \cdot 10^{-5}(\text{cm}) \cdot 4.184 \cdot 10^7(\text{erg/cal}) \cdot 10^3(\text{cal/kcal})}$$

$$E = 113\text{kcal/mole}$$

the most abundant (99.8 per cent) oxygen isotope. Under this system, molecular weight values are about 1.0002 times those commonly used. A recent conference of the International Commission on Atomic Weight (1961) adopted a value of 12 for the carbon-12 isotope as a standard.

The weights of molecules range from a value of about two for the hydrogen molecule to several millions for some virus molecules and certain polymeric compounds. Molecular dimensions accordingly range from a diameter of about 4Å for the hydrogen molecule to several thousand angstroms—which has permitted viewing single large molecules in the electron microscope. Molecular sizes are generally much smaller and are not measured directly, but are deduced from x-ray diffraction studies of ordered groups of molecules in the crystalline state or from the physical properties such as hydrodynamic behavior of molecules in the gaseous or liquid state.

Many methods for determining molecular weights which are described below depend fundamentally on counting the number of molecules present in a given weight of sample. However, any usable sample contains a very large number of molecules: at least ten trillion of the largest known molecules are present in the smallest weight measurable on a sensitive balance. Therefore, an indirect count is made by measuring physical properties which are proportional to the large number of molecules present. A consequence of the large number of molecules sampled is the averaging of any variations in content of atomic isotopes in individual molecules, so that normal isotopic fluctuations lead to no measurable deviation of molecular weight values. Abnormally high concentrations of isotopes in radiation products may, however, produce altered molecular weights.

The term molecular weight is properly applied to compounds in which chemical bonding of all atoms holds the molecule together under normal conditions (see BOND, CHEMICAL). Thus, covalent compounds, as represented by many organic substances, usually are found to have the same molecular weight in the solid, liquid, and gaseous states. However, substances in which some bonds are highly polar may exist as unionized or even associated molecules in the gaseous state and in nonpolar solvents, but they may be ionized when dissolved in polar solvents. For example, ferric chloride exists in the gaseous state as FeCl_3 at high temperatures, as Fe_2Cl_6 at lower temperatures as well as in nonpolar solvents, but reverts to FeCl_3 in solvents of moderate polarity, and becomes ionic in water solutions—as chloride ions and hydrated ferric ion. Similarly, acetic acid and some other carboxylic acids associate as dimers in the vapor state and in solvents of low polarity, but exists as monomers with progressive ionization as the solvent polarity increases.

Truly ionic compounds, such as most salts, exist only as ions in the solid and dissolved states, so that the term molecule is not applicable and is not commonly used. Instead, the term,

formula weight, is used; this denotes the sum of the atomic weights in the simplest formula representation of the compound. If a broad definition of a molecule as an aggregate of atoms held together by primary valence bonds is adopted, then salts in the crystalline state would appear to have a molecular weight which is essentially infinite and limited only by the size of the crystal, since each ion is surrounded by several ions of opposite polarity to which it is attached by ionic bonds of equal magnitude.

A further complication in the definition of molecular weights occurs with inorganic polymers whose polymeric nature is clearly evident in both their crystal structure and their highly viscous behavior in the molten state. However, the magnitude of their molecular weights often cannot be found by conventional methods because they are either insoluble or react with solvents, with consequent degradation. These examples indicate that the molecular weight often depends on the conditions used for measurement and must be specified where compounds subject to association, dissociation or reaction are studied.

The history of the clarification of molecular weight concepts is of considerable interest, since this was so intimately related to other developments in chemical knowledge. Although Dalton had published a table of atomic weights in 1808, and by 1825 molecular formulas, derived from combining weights, were in use, many misconceptions of these formulas remained until about 1860. Then evidence from chemical reactions and from measurements of vapor densities firmly established the formulas of many inorganic and simple organic compounds as they are represented today. The vapor density method, based on Avogadro's hypothesis, was thus the first molecular weight method and continues to be useful for compounds that can be easily volatilized. It was not until 1881 that Raoult showed that the depression of freezing points was proportional to the molar concentration of solute. In 1884, van't Hoff related the osmotic pressure of solutions to the vapor pressure, boiling point, and freezing point behavior, and these methods were quickly put into use for determining molecular weights. The abnormal physical properties of salt solutions were explained in 1887 by the ionization theory of Arrhenius, and the very careful measurements of many of these properties furnished the strongest confirmation of the theory. While these measurements provided the most precise determinations of the extent of dissociation of weak electrolytes, they also contributed to the development of the Debye-Hückel theory for strong electrolytes.

Molecular Weight Distributions. There are many systems, particularly among the polymers and proteins, which consist of molecules of various chain lengths, and thus of various molecular weights—so-called polydisperse systems. In such cases, molecular weight values have an ambiguous meaning, and no single such value will completely represent a sample. Various techniques for measuring molecular weights, when applied to one

of these materials, will produce values which often disagree by a factor of two or more. This disagreement arises from the different bases of the methods—for example, some methods yield so-called number-average molecular weights by determining the number-concentration of molecules in a sample, while other methods produce weight-average molecular weights which are related to the weight-concentrations of each species. Another common value is the viscosity-average molecular weight, which is related to the viscosity contribution of each species. Other bases are of importance for certain methods of study, and some of these are complex functions involving several averages. For some purposes, the determination of a single average molecular weight is sufficient for establishing relations between molecular weight and the behavior of polymers, but the type of molecular weight average must be so chosen as to have a close relation to the behavior property of interest. A more detailed knowledge of the constitution of a sample is sometimes required, particularly if several properties are to be considered, or if unusual forms of molecular weight distribution curve are present.

The problem of completely defining the molecular weight nature of polydisperse materials is most accurately solved by determining the frequency of occurrence of each molecular species and representing the results as a frequency distribution curve. Such a study is generally quite tedious, though there are a few methods which provide much of the required information in one experiment. The most common method of approximating a molecular weight distribution curve is to separate the sample into a series of fractions which differ in chain length and then to determine the average molecular weight of each fraction. The distribution curve which can be drawn from these results is often inexact, but it is the best method which is commonly available. Obviously, such a study requires so much effort that it can be applied only to materials of great interest. Some recent improvements in fractionation methods based on the fractional solution of material finely dispersed in a column appear to offer greater speed of separation and improved sharpness of the fractions, which should overcome some objections. The ultracentrifuge is less commonly used for determining molecular weight distributions in a single experiment, partly because of its cost and the complexity involved in the analysis of data.

Uses. Molecular weight measurements, in conjunction with the law of combining proportions, have enabled the atomic weights of elements in compounds to be determined. When the atomic weights are known, molecular weight measurements permit the assignment of molecular formulas. Other applications to compounds of low molecular weight allow determination of the extent of ionization of weak electrolytes, and the extent of association of some uncharged compounds which aggregate. The study of molecular weights is becoming increasingly valuable in assessing the effects which various molecular

species of a polymer sample have on the physical properties of the product. Through such knowledge, the synthetic process may be modified to improve the properties of polymers.

Methods of Measurement. Many physical and certain chemical properties vary substantially with the molecular weight of compounds, and these properties are the bases of all molecular weight methods. The summary given in this section includes principally the methods which are most frequently used or have general applicability. The choice of the most suitable method for a given sample depends on its state (gas, liquid, or solid), the magnitude of the molecular weight and the accuracy required in its determination, as well as on the stability of the compound to physical or chemical treatment. Some mention of the applicability of the methods in these regards is given wherever possible.

Gases and Liquids. Avogadro's hypothesis (1811) that equal volumes of different gases contain the same number of molecules under the same conditions made it possible to find how many times heavier a single molecule of one gas is than that of another. Thus, relative molecular weights of all gases could be established by comparing the weights of equal volumes of gases. The significance of the idea and utilization of this method were first clearly demonstrated by Cannizzaro in 1858, and this represents the first available method for determining molecular weights. With the additional information from chemical experiments on the number of atoms of each kind present in each molecule, the relative weights of each atom were obtained. The assumption of the integral value, 16, for the atomic weight of oxygen (to give a value close to unity for the lightest element, hydrogen) then enabled molecular weights of all gaseous compounds to be determined. The method obviously can be applied to other molecules which normally occur in the liquid state but can be volatilized by heating. The Dumas and Victor Meyer methods are most used for molecular weight determinations with liquids in this way. These methods have been refined so that gas densities can now be determined with an accuracy of 0.02 per cent, and extremely small weights of material (about 1 μ g) can be similarly studied with somewhat less accuracy. High temperatures up to 2000°C have been used to study substances which are volatilized only with difficulty, provided decomposition can be avoided.

Solids Measured by Colligative Methods. It has been shown that nonvolatile molecules dissolved in a solvent affect several physical properties of the solvent in proportion to the number of solute molecules present per unit volume. Among these properties are a decrease of the vapor pressure of the solvent, a rise in its boiling point, a decrease in its freezing point, and the development of osmotic pressure when the solution is separated from the solvent by a semipermeable membrane. Properties such as these which are related to the number of molecules in a sample rather than to the type of molecule are called

colligative properties. They are the basis for some of the most useful techniques for molecular weight determination. The magnitude of the effects and the ease of measurement differ greatly, so that certain of the colligative properties are preferred for this purpose. For example, an aqueous solution containing 0.2 gram of sucrose (molecular weight 342) in 100 ml has a vapor pressure 0.01 per cent less than that of the solvent, a boiling point 0.003°C greater, and a freezing point 0.011°C lower than the solvent, but will develop an osmotic pressure of 150 cm of water. Since the effects are related to the number-concentration of solute molecules, each method leads to a number average molecular weight if the sample consists of a mixture of molecules of different sizes. Accurate results with any of the techniques are obtained only when measurements at a series of concentrations are extrapolated to infinite dilution where the system becomes ideal, i.e. is not affected by interactions between molecules.

Direct vapor pressure measurements with a differential manometer are generally limited to the larger depressions produced by low molecular weight solutes, while refined techniques such as isothermal distillation require the most exact control of conditions. Isopiestic methods allow the comparison of the vapor pressure of solutions of an unknown with those containing a known substance, and several modifications have been used more than other vapor pressure methods. Ebulliometric techniques which depend on the elevation of the boiling point of a solvent are often used for solutes of low molecular weight and find some use for large molecules. Since boiling points are highly sensitive to the atmospheric pressure, it is either necessary to control pressure very precisely, or more commonly to measure the boiling points of both the solvent and solution simultaneously. Often a differential thermometer is employed to determine only the difference of the two temperatures, and these devices have been made so sensitive that molecular weights as large as 30 000 have sometimes been studied. Techniques involving the lowering of the freezing point of a solvent (cryoscopic methods) are much used for rapid approximate determinations of molecular weights in the identification of organic compounds. For this purpose a substance such as camphor, which is a good solvent for many organic compounds and has a large molar depression constant, is often chosen to magnify the difference in freezing point of the solvent and the solution of the unknown. Since freezing-point depressions are not sensitive to atmospheric pressure, they are easier to measure accurately than the methods described above, and much use has been made of them for precise studies of solutes having low molecular weights. The possibility of association or ionization of the solute must be considered with any of these methods, since these effects will greatly influence the result.

Osmotic pressures are so much larger than any other colligative property that they are most widely used for molecular weight measurements,

particularly for long-chain polymers where the high sensitivity of the method is required. For accurate measurements, a membrane is required which permits the flow of solvent through its pores but completely holds back solute molecules. This condition is best satisfied where there are large differences in size of the solute and solvent molecules or of their affinity for the membrane. Membranes made from cellulose compounds are often successfully used for polymers which contain little material with molecular weights below about 10 000. Below this molecular weight the pore size of the satisfactory membranes is so small that solvent flow is very slow, and thus a very long time is required to reach constant osmotic pressure. In spite of this handicap, some of the most precise osmotic pressure measurements have been obtained with aqueous solutions of sucrose and similar small solutes by the use of membranes prepared by precipitating such materials as copper ferrocyanide in the pores of a solid support. The upper limit of molecular weights satisfactorily measured by osmometry is usually about 500 000, which is fixed by the lowest pressures that can be measured precisely and by the maximum concentrations of material which still give satisfactory extrapolations to infinite dilution. In comparing various colligative properties for the characterization of polymers, osmometry has the advantage that it is unaffected by the presence of impurities of very low molecular weight which will diffuse through membranes able to retain the polymer, whereas the other properties are greatly affected by the same impurities.

Modern instrumentation has provided commercial instruments utilizing several of these colligative properties for routine, accurate measurements in very short time and with small samples. This is true for boiling point, vapor pressure, and freezing point measurements of molecular weights up to several thousand, and for membrane osmotic pressure measurements of high molecular weight samples.

X-ray Diffraction. X-ray diffraction analysis is a powerful method for determining exact molecular weight and structural characteristics of compounds in their crystalline state. However, the method is complicated and slower than many techniques which provide molecular weights of accuracy sufficient for many purposes and so is usually employed only when the additional structural information is needed. The sample to be examined must have a high degree of crystalline order and is preferably a single crystal at least 0.1 mm in size; such samples are prepared fairly readily from many inorganic and non-polymeric organic compounds. Alternatively, crystalline powders of certain crystal types may provide suitable results. Diffraction patterns are then obtained by one of several methods, and the angular positions of the reflections are used to calculate the lattice spacings, and thus the size of the unit cell. This unit cell is the smallest volume unit which retains all geometrical features of the crystalline class, and it contains a small integral

number of molecules. A rough estimate of the molecular weight of the compound is needed from a determination by an independent method in order to obtain this integral number. Finally, the resultant molecular volume is multiplied by the exact bulk density of the crystal and by the avogadro number to yield the molecular weight (see X-RAY DIFFRACTION).

Light Scattering. Measurements of the intensity of light scattered by dissolved molecules allow the determination of molecular weights. Most commonly the method is used for polymers above 10 000 units, though under optimum conditions molecular weights as low as 1000 have been determined. Since the intensity scattered by a given weight of dissolved material is directly proportional to the mass of each molecule, a weight-average value of the molecular weight is obtained for a polydisperse system. An average dimension of the molecule can also be obtained by a study of the angular variation of scattered light intensity, provided some dimension of the molecules exceeds a few hundred angstroms. The interaction between dissolved molecules substantially affects the intensity of scattered light so that extrapolation to infinite dilution of data collected at several polymer concentrations is required. The method has been so well developed in the last decade that it is now probably the most used method for determining absolute molecular weights of polymers. It is more rapid than osmometry and provides information on sizes which is furnished by few other methods. The greatest problem encountered is in the removal of suspended large particles which otherwise would distort the angular scattering pattern of the solutions. This is rather easily accomplished by filtration in some cases, but it may be a formidable difficulty for particles which are highly solvated or are peptized by the molecules to be studied. Auxiliary information is required on the refractive index increment of the sample, i.e., the change in refractive index of the solvent produced by unit concentration of the sample. This information is supplied by a differential refractometer using the same wavelength of light as that employed in measurements of the intensity of scatter.

The Ultracentrifuge. The sedimentation of large molecules in a strong centrifugal field enables the determination of both average molecular weights and the distribution of molecular weights in certain systems. When a solution containing polymer or other large molecules is centrifuged at forces up to 250 000 times gravity, the molecules begin to settle, leaving pure solvent above a boundary which progressively moves toward the bottom of the cell. This boundary is a rather sharp gradient of concentrations for molecules of uniform size, such as globular proteins, but for polydisperse systems, the boundary is diffuse, the lowest molecular weights lagging behind the larger molecules. An optical system is provided for viewing this boundary, and a study as a function of the time of centrifuging yields the rate of sedimentation for the single

component or for each of many components of a polydisperse system. These sedimentation rates may then be related to the corresponding molecular weights of the species present after the diffusion coefficients for each species are determined by independent experiments. Both the sedimentation and the diffusion rates are affected by interactions between molecules, so that each must be studied as a function of concentration and extrapolated to infinite dilution as is done for the colligative properties. The result of this detailed work is the distribution of molecular weights in the sample which is available by few other methods. At present, this method is only partly satisfactory for molecular weight determinations with linear polymers because of the large concentration dependence of the diffusion coefficients. Difficulties have been found in reliably extrapolating diffusion coefficients beyond the lowest polymer concentrations which are experimentally attainable at present.

A modification of the sedimentation method which avoids the study of diffusion constants is the sedimentation equilibrium method in which molecules are allowed to sediment in a much weaker field. Under these conditions, the sedimenting force is balanced by the force of diffusion, so that after times from a day to two weeks molecules of each size reach different equilibrium positions, and the optical measurement of the concentration of polymer at each point gives the molecular weight distribution directly. However, again extrapolation to infinite dilution must be used to overcome interaction effects. The chief difficulty here is the long time of centrifuging required, and the necessary stability of the apparatus during the period.

A newer and somewhat faster technique, the Archibald method, permits the determination of weight-average molecular weights of polymers by analysis of the concentration gradient near boundaries soon after sedimentation begins.

Chemical Analysis. When reactive groups in a compound may be determined exactly and easily, this analysis may be used to determine the gram equivalent weight of the substance. This is the weight in grams which combines with or is equivalent to one gram-atomic weight of hydrogen. This equivalent weight may then be converted to the molecular weight by multiplying by the number of groups per molecule which reacted (provided they each are also equivalent to one hydrogen). If the number of reactive groups in the molecule is not known, then one of the physical methods for determining molecular weight must be used instead. The chemical method is convenient and often used for the identification of organic substances containing free carboxyl or amino groups which can readily be titrated, and for esters which can be saponified and determinations made of the amount of alkali consumed in this process. The equivalent weights of ionic substances containing, for example, halide or sulfate groups may also be determined by titration or by gravimetric analysis of insoluble compounds

formed with reagents which act in a stoichiometric fashion. In the titration of acids, the "neutral equivalent" is the weight of material which combines with one equivalent of alkali, and a similar definition applies to the "saponification equivalent" of esters. If only one carboxyl or ester group is present in the molecule, these values equal the molecular weight of the compound.

In a similar way, if the terminal groups on polymer chains can be determined by a chemical reaction without affecting other groups in the molecule, the equivalent weight or molecular weight of the polymer may be obtained in certain cases. For polydisperse systems, a number-average value of the molecular weight is obtained because the process essentially counts the total number of groups per unit weight of sample. Since the method depends on the effect of a single group in a long chain, its sensitivity decreases as the molecular weight rises, and so is seldom applicable above molecular weights of 20 000. Particularly at high molecular weights, the method is very sensitive to small amounts of impurities which can react with the testing reagent, so that careful purification of samples is desired.

It is also important to know that impurities or competing mechanisms of polymerization do not lead to branching or other processes which may provide greater or fewer reactive groups per molecule. The analysis for end groups must be carried out under mild conditions which do not degrade the polymer, since this would also lead to lower molecular weight values than expected. Labeling of end groups either with radioactive isotopes or with heavy isotopes which can be analyzed with the mass spectrometer provides a rapid and convenient analysis for end groups. This labeling can be accomplished with a labeled initiator if this remains at the chain ends, or after polymerization is complete, by exchange of weakly bonded groups with similar groups in a labeled compound. Molecular weight determinations by end group analysis are often used for condensation polymers of lower molecular weights and are especially valuable in studying degradation processes in polymers.

MOLECULES AND MOLECULAR STRUCTURE

A molecule is a local assembly of atomic nuclei and electrons in a state of dynamic stability. The cohesive forces are electrostatic, but, in addition, relatively small electromagnetic interactions may occur between the spin and orbital motions of the electrons, especially in the neighborhood of heavy nuclei. The internuclear separations are of the order of 1 to 2×10^{-10} metres, and the energies required to dissociate a stable molecule into smaller fragments fall into the 1 to 5 eV range. The simplest diatomic species is the hydrogen molecule-ion H_2^+ with two nuclei and one electron. At the other extreme, the protein ribonuclease contains 1876 nuclei and 7396 electrons per molecule.

Historically, molecules were regarded as being formed by the association of individual atoms. This led to the concept of *valency*, i.e., the number of individual chemical bonds or linkages with which a particular atom can attach itself to other atoms. When the electronic theory of the atom was developed, these bonds were interpreted in terms of the behavior of the valence, or outer shell, electrons of the combining atoms. Each atom with a partly filled valence shell attempts to acquire a completed octet of outer electrons, either by electron transfer, as in (a), to give an electrovalent bond, resulting from Coulombic attraction between the oppositely charged ions

(W. Kossel, 1916); or by electron sharing, as in (b) and (c), to give a covalent bond (G. N. Lewis, 1916). In (b), each chlorine atom donates one electron to form a *homopolar* bond, which is written $\text{Cl}-\text{Cl}$ where the bar denotes on this theory one single bond, or shared electron pair. In (c), the nitrogen-oxygen bond is formed by two electrons donated by only the nitrogen atom, giving a *semipolar*, or *coordinate-covalent* bond, which is written $\text{R}_3\text{N}^+-\text{O}^-$, and which is electrically polarized. Double or triple bonds result from the sharing of four or six electrons between adjacent atoms, as in ethylene (d) and acetylene (e) respectively.

However, difficulties arise in describing the structures of many molecules in this fashion. For example, in benzene (C_6H_6), a typical aromatic compound, the carbon nuclei form a plane regular hexagon, but the electrons can only be conventionally written as forming alternate single and double bonds between them. Furthermore, an electron cannot be identified as coming specifically from any one of these bonds upon ionization. Such difficulties disappear in the quantum-mechanical theory of a polyatomic molecule, whose electronic wave function can be constructed from nonlocalized electron orbitals extending over all of the nuclei. The concept of valency is not basic to this theory, but is simply a convenient approximation by which the electron density distribution is partitioned in different regions in the molecule.

Molecular compounds consist of two or more stable species held together by weak forces. In *clathrates*, a gaseous substance such as SO_2 , HCl , CO_2 or a rare gas is held in the crystal lattice of a solid, such as β -quinol, by van der Waals-London dispersion forces. The *gas hydrates*, e.g., $Cl_2 \cdot 6H_2O$, contain halogen molecules similarly trapped in ice-like structures. The hydrogen bond, with energy ~ 0.25 eV, is responsible not only for the high degree of molecular association in liquids such as water ($O-H \cdots O-H \cdots$) but also for such molecules as the formic acid dimer

which contains two hydrogen bonds indicated by dashed lines. *Molecular complexes* vary greatly in their stability; in donor-acceptor complexes, electronic charge is transferred from the donor (e.g., NH_3) to the acceptor (e.g., BF_3), as in a semipolar bond. The $BF_3 \cdot NH_3$ complex has a binding energy with respect to dissociation into NH_3 and BF_3 of 1.8 eV. The bond here is relatively strong; the electron transfer can occur between the components in their electronic ground states. On the other hand, in weaker complexes such as $C_6H_6 \cdots I_2$, with binding energy of about 0.06 eV, there is only a fractional transfer of charge from benzene to iodine. The actual ionic charge-transfer state lies at much higher energy than the ground state of the complex.

The discovery of $XePtF_6$ by Bartlett (1962) has been followed by the synthesis of many other rare gas compounds whose existence was not predicted by classical valency theories. Compounds such as XeF_2 , XeF_4 , XeF_6 and $XeOF_4$ are quite stable, the average $Xe-F$ bond energy in the square planar molecule XeF_4 being 1.4 eV.

A molecule X is characterized by:

(1) A *stoichiometric formula* $A_aB_bC_c \cdots$ where a, b, c, \dots are the numbers of atoms of elements A, B, C, \dots that it contains. The ratio $a : b : c : \dots$ is found by chemical analysis for these elements.

The absolute values of a, b, c, \dots are then fixed by determination of the *molecular weight* of X . For a volatile substance, the gas density of X and of a gas of known molecular weight are compared at the same temperature and pressure. The molecular weights are in the ratio of the gas densities, since *Avogadro's principle* states that equal volumes of gases at the same temperature and pressure contain the same numbers of molecules. For a nonvolatile substance, a known weight can be dissolved in a solvent, and the resultant lowering of vapor pressure, elevation of the boiling point, or depression of the freezing point of the solvent can be measured. Each of these properties depends upon the number of molecules of solute present, so the number of molecules per unit weight of X is found and, hence, the molecular weight. For substances of high molecular weight such as proteins (molecular weight $\sim 34\,000$ – $200\,000$) or polymers, the molecular weight is found from osmotic pressure measurements or the rate of sedimentation in a centrifuge. The molecular weight of a molecule in crystalline form is determined when the density of the crystal and the dimensions of the unit cell from x-ray analysis are both known. Finally, for stable volatile compounds, it is often possible to form the ion X^+ and pass this through a mass spectrograph to determine the molecular weight.

(2) The spatial distribution of the nuclei in their mean equilibrium or "rest" positions. At an elementary level, this is described in geometrical language. For example, in carbon tetrachloride, CCl_4 , the four chlorine nuclei are disposed at the corners of a regular tetrahedron, and the carbon nucleus is at the center. In the $[CoCl_4]^{2-}$ ion, the arrangement of the chlorine nuclei about the central metal nucleus is also tetrahedral, whereas in $[PdCl_4]^{2-}$ it is planar.

At a more sophisticated level, each molecule is classified under a *symmetry point group*. Most nonlinear molecules possess only 1, 2, 3, 4 or 6-fold rotation axes, and belong to one of the 32 crystallographic point groups. For example, the pyramidal ammonia molecule NH_3 has a three-fold rotation axis C_3 through the nitrogen nucleus and three reflection planes σ_v intersecting at this axis, and belongs to the $C_{3v}(3m)$ point group. Tetrahedral molecules CX_4 belong to the $T_d(\bar{4}3m)$ point group. Linear diatomic and polyatomic molecules belong to either of the continuous point groups $D_{\infty h}$ or $C_{\infty v}$ according to whether a center of symmetry is present or not.

The symmetry classification does not define the geometry of a molecule completely. The values of certain *bond lengths or angles* must also be specified. In carbon tetrachloride, it is sufficient to give the $C-Cl$ distance (1.77×10^{-10} meters) since classification under the T_d point group implies that all four of these bonds have equal length and the angle between them is $109^\circ 28'$. In ammonia, both the $N-H$ distance (1.015×10^{-10} meters) and the angle HNH (107°) must be specified. In general, the lower the molecular symmetry, the greater is the number of such

independent parameters required to characterize the geometry. Information about the symmetry and internal dimensions of a molecule is obtained experimentally by SPECTROSCOPY, ELECTRON DIFFRACTION, NEUTRON DIFFRACTION and X-RAY DIFFRACTION.

(3) The *dynamical state* is defined by the values of certain observables associated with orbital and spin motions of the electrons and with vibration and rotation of the nuclei, and also by symmetry properties of the corresponding stationary-state wave functions. Except for cases when heavy nuclei are present, the total electron spin angular momentum of a molecule is separately conserved with magnitude Sh , and molecular states are classified as singlet, doublet, triplet, ... according to the value of the multiplicity $(2S+1)$. This is shown by a prefix superscript to the term symbol, as in atoms.

The Born-Oppenheimer approximation permits the molecular Hamiltonian H to be separated into a component H_e that depends only on the coordinates of the electrons relative to the nuclei plus a component depending upon the nuclear coordinates, which in turn can be written as a sum $H_v + H_r$ of terms for vibrational and rotational motion of the nuclei (we may ignore translation here). The eigenfunctions Ψ of H may correspondingly be factorized as the product $\Psi_e \Psi_v \Psi_r$ of eigenfunctions of these three operators, and the eigenvalues E decomposed as the sum $E_e + E_v + E_r$. In general, we find $E_e \gg E_v > E_r$.

Electronic states of molecules are classified according to the symmetry properties of Ψ_e (which forms a basis for an irreducible representation of the molecular point group). Thus ${}^3B_{1u}$ is a term symbol for benzene (D_{6h} point group) that denotes a triplet electronic state whose wave function transforms like the B_{1u} representation of the group. In the case of diatomic and linear polyatomic molecules, the term symbol shows the magnitude of the conserved component of orbital electronic angular momentum Λh about the axis, states being classified as Σ , Π , Δ , ... according to $\Lambda = 0, 1, 2, \dots$. The superscript $+$ or $-$ shows the behavior of Ψ_e for a linear molecule upon reflection in a plane containing the molecular axis; for centrosymmetric linear molecules ($D_{\infty h}$ point group) the subscript g or u shows the parity $+1$ or -1 respectively for Ψ_e with respect to inversion at the center.

The vibrational wavefunction Ψ_v can be approximated by a product of $3N-6$ harmonic oscillator wave functions ψ_i , each a function of a normal displacement coordinate Q_i ,

$$\Psi_v = \prod_{i=1}^{3N-6} \psi_i(Q_i)$$

The product is $(3N-5)$ for a linear molecule; N is the number of nuclei. Each oscillatory mode can be excited with quanta $v_i = 0, 1, 2, \dots$. When $v_i = 0$, ψ_i transforms like the totally symmetrical representation of the molecular point group;

when $v_i = 1$, ψ_i transforms like Q_i . The symmetry of Ψ_v under the molecular point group is found from the direct product for all the ψ_i . The vibrationless ground state with $v_1 = v_2 = \dots = 0$ is always totally symmetrical.

Each rotational state is characterized by a value for the quantum number J , where $J(J+1)\hbar^2$ is the squared angular momentum for rotation of the nuclei (apart from spin). If I_a , I_b and I_c denote the moments about the principal axes of inertia of the molecule, then a spherical top has $I_a = I_b = I_c$; a molecule with two principal moments equal is either a prolate ($I_c = I_b > I_a$) or an oblate ($I_c > I_b = I_a$) symmetric top; if $I_c \neq I_b \neq I_a$, the top is asymmetric. Symmetric top molecules have C_n symmetry axes with $n \geq 3$ and belong to point groups with degenerate representations. The component $K\hbar$ of rotational angular momentum about the top axis is conserved and the rotational levels are also characterized by the value of the quantum number $K = 0, 1, 2, \dots, J$. A symmetry classification is made for Ψ_r under the rotational subgroup of the molecular point group. Finally, each eigenstate is described as $+$ or $-$ according to the parity of Ψ under inversion in a space-fixed coordinate system.

(4) In order to distinguish between different electronic states Ψ_e of the same symmetry and spin multiplicity, a further classification is obtained by expanding Ψ_e as a product of n single-electron wave functions ϕ_i , each a function of the coordinates of one of the n electrons in the molecule.

$$\Psi_e = (n!)^{-1/2} \det[\phi_1(1)\phi_2(2)\phi_3(3) \dots \phi_n(n)]$$

where $(n!)^{-1/2}$ is a normalization factor. Each of the molecular orbitals (MO's) ϕ_i is constructed to transform like an irreducible representation of the molecular point group and is usually formed by linear combination of atomic orbitals (LCAO) χ_i centered upon the individual nuclei

$$\phi_i = \sum_p C_{ip} \chi_p$$

The MO's are written in order of decreasing energy necessary to ionize the electrons which occupy them, and electrons are assigned to the MO's in accordance with the Pauli principle. For example, the electronic ground state of ammonia (C_{3v} point group) is written

$$(1a_1)^2(2a_1)^2(1e)^4(3a_1)^2 \quad {}^1A_1$$

where the superscripts show the distribution of the ten electrons among three MO's of a_1 symmetry and one of e symmetry, the electrons in the $(3a_1)$ orbital being most readily ionized. The symmetry of the resultant molecular wavefunction Ψ_e is found by taking direct products for each orbital occupied by an electron. Here Ψ_e belongs to the totally symmetrical representation (and is also singlet). Excited electronic states are obtained by promoting electrons into orbitals with higher energies, but the molecular symmetry in such

states often differs from that in the ground state, as a result of changes in geometry.

MOMENTUM. See IMPULSE AND MOMENTUM.

MÖSSBAUER EFFECT

The Mössbauer effect is the phenomenon of recoilless resonance fluorescence of gamma rays from nuclei bound in solids. It was first discovered in 1958 and brought its discoverer, Rudolf L. Mössbauer, the Nobel prize for physics in 1961. The extreme sharpness of the recoilless gamma transitions and the relative ease and accuracy in observing small energy differences make the Mössbauer effect an important tool in nuclear physics, solid-state physics and chemistry.

Resonance fluorescence involves the excitation of a quantized system (the absorber) from its ground state (0) to an excited state (1) by absorption of a photon emitted from an identical system (the source) decaying from state (1) to (0). The parameters characterizing the nuclear resonance process for some typical isotopes are illustrated in Fig. 1.

To conserve energy and momentum in the emission and absorption processes, each system, the source and absorber, must acquire a recoil energy R equal to $E^2/2Mc^2$, where E is the photon energy. M is the mass of the recoiling system and c is the speed of light. The energy available for the excitation of the absorber is thus reduced by $2R$, and resonance fluorescence can be achieved only if the missing energy $2R$ is not larger than the widths of the levels involved. Before 1958, it was thought that for all gamma transitions the width required to get overlap between the emission and the absorption line was much larger than the natural width Γ , where Γ is related to the half-life $T_{1/2}$ of the excited nuclear level by the expression $\Gamma T_{1/2} = 4.55 \times 10^{-16} \text{ eV sec}$. In fact, techniques had been developed to compensate for the recoil energy loss by applying large Doppler shifts with an ultracentrifuge or through

thermal motion. These methods necessarily broaden the intrinsically narrow lines thereby reducing the absorption cross section.

Modifying a theory of W. E. Lamb, Mössbauer demonstrated that in some cases these difficulties may be removed by embedding the source and absorber nuclei in a crystal. Being part of a quantized vibrational system, these nuclei interact with the lattice by exchange of vibrational quanta or phonons only. If the characteristic phonon energy is large compared to the recoil energy R for a free nucleus, the probability for the emission of a gamma ray without a change in the vibrational state of the lattice is large. For such a zero phonon transition, the lattice as a whole absorbs the recoil momentum and the recoil energy loss is negligibly small. At the same time, the emission and absorption lines achieve the natural width Γ .

For an atom bound by harmonic forces, the fraction f of events without recoil energy loss is given by $f = \exp(-4\pi^2 \langle x^2 \rangle / \lambda^2)$. Here $\langle x^2 \rangle$ is the mean square displacement of the radiating atom taken along the direction of the photon with wavelength λ . In an environment of lower than cubic symmetry, $\langle x^2 \rangle$, and therefore f , may be anisotropic. A large recoilless fraction may be obtained when $\langle x^2 \rangle$ is small and λ large. The former condition implies small vibrational amplitude and thus low temperature, high vibrational frequency and large mass M , while the latter implies low photon energy, E . Both conditions imply small recoil energy R .

Recoilless transitions can also occur in amorphous substances like glasses and high-viscosity liquids. For the latter, the diffusive motion superimposed on the thermal vibration results in a broadening of the Mössbauer line.

For all Mössbauer isotopes, the nuclear half-life $T_{1/2}$, typically 10^{-8} second, is very long compared to the period of the lattice vibrations, typically 10^{-11} second. A conceivable first-order Doppler shift of the Mössbauer line due to the thermal motion will therefore average out to zero. The second-order Doppler effect, however, leads to an observable shift, sometimes called the temperature shift. The photons emitted by a source nucleus moving with a mean square velocity $\langle v^2 \rangle$ are lower in energy by a fraction $\langle v^2 \rangle / 2c^2$ as compared to the photons emitted at rest. Similarly the transition energy of a moving absorber nucleus appears lower to the incident photon by a fraction $\langle v^2 \rangle / 2c^2$. In principle, the two shifts may be different whenever the source and absorber are of different composition and/or temperature.

Mössbauer performed his original experiment with Ir^{191} at 88 K, obtaining a recoilless fraction of 1 per cent. Since the natural line width in Ir^{191} , as in most other Mössbauer nuclides, is extremely narrow, Mössbauer was able to alter the degree of overlap between the emission and absorption lines by simply moving the source relative to the absorber at speeds v of the order of 1 mm/sec. Thus the gamma rays were slightly shifted in energy via the first-order Doppler effect by an

FIG. 1

amount $\Delta E = Ev/c$. By plotting the transmission through the absorber as a function of the relative source-absorber velocity, one thus obtains the characteristic Mössbauer velocity spectrum which exhibits the shape of the resonance curve. From such a plot, one can determine the recoilless fraction, the lifetime of the excited state and any possible energy differences between the emission and the absorption line.

With extreme care, it is possible to determine energy differences of the order of $1/1000$ of the line width Γ . The latter typically varies with isotope from 10^{-10} to 10^{-15} times the actual gamma ray energy E . The Mössbauer effect therefore enables one to detect extremely small changes in this energy. One of the earliest applications of this great precision was the laboratory verification of the gravitational red shift by Pound and Rebka. According to Einstein's theory, photons have an apparent mass $m = E/c^2$. Thus if they fall toward the earth through a distance H , their energy increases by $\Delta E = mgH$, so that

$\Delta E/E = gH/c^2 \approx 10^{-16}$ per meter. Using Fe^{57} , which has a large recoilless fraction, and for which $\Gamma/E \approx 3 \times 10^{-13}$, the desired effect was observed when the photons were sent down the 22-meter tower at Harvard University.

It is well known from optical and high-frequency spectroscopy that a nucleus interacting with its environment through its charge distribution and magnetic moment can give rise to hyperfine shifts and splittings of the order of 10^{-6}eV to 10^{-9}eV . In Mössbauer experiments, such energy differences can readily be measured since the line width of the recoilless transitions is of the same order of magnitude. Perhaps, therefore, the most useful feature of the Mössbauer effect is that it may be used to obtain nuclear properties if the fields acting on the nucleus are known, and conversely, it is a powerful tool for probing solids once the various interactions are calibrated, i.e., the nuclear properties have been determined. Some representative results obtained with Fe^{57} are illustrated in Fig. 2.

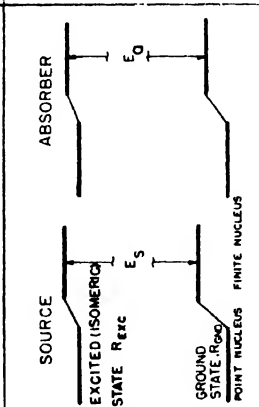

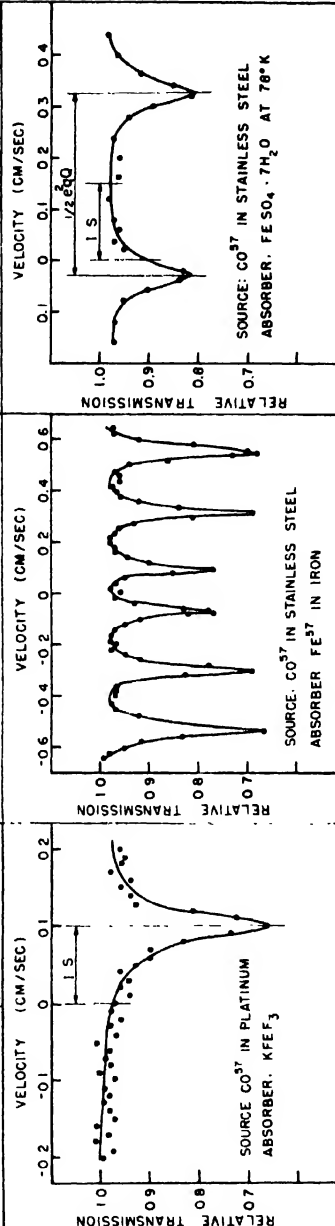

NUCLEAR HYPERFINE INTERACTION FOR Fe^{57}					
MULTIPOLE ORDER	ELECTRIC MONOPOLE · ISOMER SHIFT	MAGNETIC DIPOLE : ZEEMAN SPLITTING	ELECTRIC QUADRUPOLE		
NUCLEAR PROPERTY	CHANGE IN CHARGE RADIUS $\frac{\delta R}{R}$	MAGNETIC MOMENT μ	ELECTRIC QUADRUPOLE MOMENT Q		
ATOMIC PROPERTY	s - ELECTRON DENSITY $ \psi(o) ^2$	INTERNAL MAGNETIC FIELD $H(o)$	ELECTRIC FIELD GRADIENT q		
INTERACTION ENERGY	$IS_0 = E_0 - E_s = \frac{4\pi}{5} Ze^2 R^2 \left(\frac{\delta R}{R} \right) \psi(o) ^2 - \psi(o) ^2$ $E_M = \frac{\mu H(o) I_z}{I}$ $E_Q = eqQ \frac{3I^2 - I(I+1)}{4I(2I-1)}$

FIG. 2.

The most basic of these interactions is the effect of the finite nuclear size which, in general, is different for the ground state and the excited state. The electrostatic interaction of the nuclear charge with the s -electrons overlapping it raises the nuclear energy levels by an amount depending on the charge radii and s -electron density at the nucleus. Therefore under proper conditions, there appears a shift in the Mössbauer resonance, the isomer shift, which is proportional to $(\delta R/R) \delta|\psi(0)|^2$, where $\delta R/R$ is the fractional change in the nuclear radius during the decay and $\delta|\psi(0)|^2$ is the difference in s -electron density between source and absorber. To determine the quantity $\delta R/R$ one compares the isomer shifts of two chemically simple absorbers, for which the s -electron density can be calculated. In the case of Fe^{57} an isomer shift exists between compounds containing ferric ions, $\text{Fe}^{3+}(3d^5)$, and ferrous ions, $\text{Fe}^{2+}(3d^6)$. Although the number of s -electrons is the same for both ions, a detailed calculation shows that the shielding through the additional $3d$ electron changes the $3s$ density at the nucleus. For I^{129} , the isomer shifts observed among different alkali iodides can be related quantitatively to the known transfer of $5p$ electrons to the ligands which affects the $5s$ density at the nucleus. Once calibrated, the isomer shift is a tool for measuring s -electron densities and is therefore of use in studying chemical bonding, energy bands in solids, and also in identifying charge states of a given atom.

One of the early successes of the Mössbauer effect was the observation of the completely resolved nuclear Zeeman splitting arising from the magnetic hyperfine interaction of Fe^{57} in ferromagnetic iron. For this isotope, as well as for most other Mössbauer isotopes, the magnetic moment of the nuclear ground state is known from magnetic resonance experiments, and the calibration is therefore straightforward. Careful analysis of the velocity spectrum for magnetic samples is sufficient in general to reveal both the desired magnetic moment and internal magnetic field. The latter yields important information about the unpaired spin density at the nucleus, which in turn is related to the exchange interaction in crystals, metals and alloys. For single crystals or magnetized samples, the intensities of the individual lines of the Mössbauer spectrum depend on the angle between the direction of the internal field and the emitted photon. From a measurement of the intensity distribution, one therefore obtains the direction of the internal magnetic field. The temperature dependence of the splitting can yield Néel and Curie temperatures and also relaxation times.

Whenever one of the nuclear levels possesses a quadrupole moment and an electric field gradient exists at the position of the nucleus, quadrupole splitting of the Mössbauer spectrum may be observed. If the quadrupole moment is known either for the ground state or for the excited state, then a Mössbauer measurement will readily yield the parameters of the field gradient tensor. Usually, however, the quadrupole moment is not known, and the field gradient tensor must be

determined from other work or else calculated from first principles. This tensor exists whenever the symmetry of the surrounding charge distribution is lower than cubic, and it is generally specified by two independent parameters. This tensor is easiest to calculate for cases of axial symmetry, in which it is characterized by one parameter, the field gradient, q . For simple ionic systems, it is possible to estimate q with some degree of certainty, and thereby determine the quadrupole moment. Once this is done, the Mössbauer effect may be used to measure field gradient tensors in more complicated systems. Such measurements yield information about crystalline symmetries, crystalline field splittings, shielding due to closed shell electrons, relaxation phenomena and chemical bonding. In addition, with single crystals, a study of the relative intensity of the various lines of the resonance spectrum as a function of angle can yield information about the orientation of the crystalline field axes and, thus, the orientation of complexes in solids. In cases where both magnetic and quadrupole splitting are present, the analysis becomes more complicated since it depends markedly upon the relative angle between the magnetic field and the axes of the electric field gradient tensor. Such cases, however, have been successfully handled for a number of antiferromagnetic compounds.

This article has only covered the basic features of the Mössbauer effect and the phenomena which affect the Mössbauer velocity spectrum in a general way. The actual application of the effect is extremely far reaching, embracing not only almost all areas of physics but also the fields of chemistry, biology, metallurgy and engineering. The reader is advised to consult the references for more information.

MOTORS, ELECTRIC

Historical. Power conversion was discovered by M. Faraday in 1831; the commutator, by J. Henry, Pixii, and C. Wheatstone (1841); the electromagnetic field, by J. Brett (1840), Wheatstone and Cooke (1845), and W. von Siemens (1867); drum armatures, by Siemens, Pacinotti, and von Alteneck; ring armatures, by Gramme (1870); and disc armatures, by Desrozières (1885)

and Fritsche (1890). Ring and disk types are now seldom used. Revolving magnetic fields (1885) and ac theory were discovered by G. Ferraris; polyphase motors and systems, by N. Tesla (1888); the squirrel-cage rotor, by C. S. Bradley (1889); and ac commutator motors, by R. Eickemeyer, E. Thomson, L. Atkinson, and others.

Principles. These are the laws of Ohm, Kirchhoff, Lenz, and Maxwell; more specifically:

(1) Moving a conductor of length l across a magnetic field of flux of density B with a velocity v generates in it an electromotive force (emf) $e = vBl \times 10^{-8}$ volts. In motors, e opposes the current i and decreases with increase in load.

(2) The force on such a conductor equals $F = 0.1 Bil$ dynes. Fig. 1 shows the directions of current and force.

FIG. 1. Direction of force due to current in a magnetic field

(3) Magnetic structures tend to move to the position of minimum reluctance with a force $F = \frac{dW}{dx}$ where W is stored magnetic energy and x is distance.

(4) The force between two coupled circuits equals

$$F = \frac{i_1^2}{2} \frac{dL_1}{dx} + i_1 i_2 \frac{dM}{dx} + \frac{i_2^2}{2} \frac{dL_2}{dx}$$

Frequently L_1 and L_2 are constant and then $F = i_1 i_2 \frac{dM}{dx}$. Here i_1 and i_2 are currents; L_1 and L_2 are total self-inductances; M is mutual inductance.

Motor Types. Of many hundreds, the most used are:

(1) *Direct-Current.* (a) *Series:* The field coils are of heavy wire in series with the armature. The torque and current are high at low speeds and low at high speeds. These motors will run away at light loads.

(b) *Shunt:* The field coils of fine wire are in parallel with the armature. The speed drops slightly and current and torque increase with load. In very small-size motors (and sometimes in fractional and integral horsepower sizes up to $7\frac{1}{2}$ hp), permanent magnet fields are used.

(c) *Compound:* Both shunt and series coils are

used on the same motor. Behavior is intermediate between (a) and (b).

The current in all dc motors satisfies the relation $I_a = \frac{V_a - E_a}{R_a}$, where $E_a = \frac{p\phi_a Z_a S}{m_a \times 60 \times 10^8}$; V_a = terminal emf; E_a = the counter electromotive force (cemf); R_a = resistance; m_a = number of paths; and Z_a = number of conductors, all for the armature; p = number of poles, S = rpm, ϕ_a = useful flux per pole. ϕ_a may be nearly constant or it may be a function of I_a .

Speed control is achieved by adjusting field, current and/or armature terminal emf, tapped series coils, or (more rarely) field reluctance or double commutator. To avoid damage in starting, either starting resistances or voltage controls are needed, except for very small-size motors.

(2) *Alternating Current.* (a) *Polyphase Induction:* These are usually 3-phase, with phase windings spaced equally in slots around the periphery to produce alternate N and S poles. When fed with polyphase current, there is set up a revolving field which turns with the speed $S = \frac{120f}{p}$ rpm and induces the cemf $E = 2.22f\phi_m Zk_w \times 10^{-8}$ volts per phase, where ϕ_m is the flux per pole and k_w is the winding factor.

With rotor open or running at synchronous speed S , each phase behaves as an inductance and draws an exciting current lagging nearly $\frac{1}{2}$ cycle behind the emf. Shaft load reduces the speed from S to $S(1 - s)$, where s is slip. When referred to primary, s generates in each rotor phase the emf sE and current

$$I_2 = \frac{sE}{\sqrt{r_2^2 + (sx_2)^2}} = \frac{E}{\sqrt{\left(\frac{r_2}{s}\right)^2 + x_2^2}}$$

where r_2 is the resistance and x_2 is the leakage reactance of rotor in ohms per phase.

The current I_2 produces the needed torque. It introduces a new magnetomotive force (mmf) which turns at synchronous speed S in the same direction as that of the stator and lags behind it in space by the electrical angle $90^\circ + \tan^{-1} \frac{x_2}{r_2}$.

To balance this mmf, the stator draws an additional component of current sufficient to carry the load. Performance can be found (as for a trans-

former) if $\frac{r_2}{s}$ is taken as variable. Three-phase motors require less material than one or two-phase motors.

(b) *Single-phase Induction:* With the rotor at rest, there is no revolving field; the motor will start in either direction only if given a push. Rotation sets up an elliptical revolving field which turns synchronously at nonuniform speed in the same direction as the rotor and pulsates between the limits ϕ_m and $\phi_m(1 - s)$. The stator current is the resultant of (stator + cross-axis) magnetizing + load + loss currents. Analysis of this type of motor is less simple than that for a polyphase motor.

Starting is with a line switch, reduced voltage (auto-transformer or "compensator," wye-delta, series resistors or chokes), wound rotors and resistors, or more elaborate schemes. For single-phase motors, auxiliary start windings (split-phase or capacitor), or repulsion-start, are used and are cut out at about $\frac{1}{2}$ speed. For sizes 0 to $\frac{1}{2}$ hp, and sometimes for sizes up to 1 hp, shaded poles are used. *Speed Control* is by reduced voltage, wound rotor, or any one of a great number of possible techniques. Induction motors are "constant speed" machines and control apparatus is more expensive than that for direct current.

(c) Synchronous: Commonly these have a stationary phase-wound armature and revolving dc field structure. When up to speed and synchronized, the revolving mmf set up by the armature stands still relative to the dc field. When the angle $(I_a, E_a) = 0$, the armature mmf poles stand midway between the field poles. When I_a lags behind E_a , the armature mmf assists the dc field coils; it opposes them when I_a leads E_a . Armature current I_a takes a value and time phase position such that the cemf E_a and current I_a are correct to carry the existing load. Important relations are $I_a = \frac{V - E_a}{Z_a}$, power converted $= mI_a E_a \cos (I_a, E_a)$, input $= mI_a V \cos (I_a, V)$, and armature copper loss $= mI_a^2 r_a$, where E_a is a function of I_a , I_f , and angle (I_a, E_a) . In general, V and E_a are prevailing in opposition and I_a increases with load.

Synchronous motors are used where the rpm must be fixed: for power factor correction, regulating transmission line voltages, or speeds too low for good induction motor performance. They are not self-starting unless special means are provided, usually squirrel-cage or phase windings in the pole faces or part windings in combination with clutches (shaft or band brake on revolving stator). Precautions against high ac voltages in the dc field coils are needed when starting. The motors will carry some load with the dc field winding open. Small sizes (reluctance types) operate without field windings. Single-phase motors are less satisfactory because of lower efficiency, tendency to severe hunting, and problems in starting.

(d) ac Commutator: These are mostly single-phase series, repulsion, or combinations of these types. However, shunt and polyphase series, shunt compound, repulsion, and adjustable speed induction motors have been built. Single-phase series motors are used in large quantities for portable tools, vacuum sweepers, household appliances, etc., and electric railways; though for this last, repulsion and combination types are also used. Rectifiers and dc motors are partly replacing ac types because they are lighter, simpler, cheaper, and can use power of all frequencies.

The ac series motor is similar to the dc motor, except for a laminated field, compensating winding (larger sizes), and precautions against low power factor and poor commutation. The runaway speed is high.

In the repulsion motor, the stator is like that of

the single-phase induction motor. The rotor is similar to a dc armature. The brushes are short-circuited and set at a small angle so that stator and rotor axes differ by some 10 to 25 electrical degrees. Once this type was frequently used as a starting arrangement for single-phase induction motors. A centrifugal arrangement short-circuited the commutator and sometimes lifted the brushes at about $\frac{1}{2}$ speed. Now they are mostly superseded by capacitor motors. There is no electrical connection between stator or line and rotor.

The stator mmf has a component (field axis) which sets up the field flux, and another at right angles to it in the armature (or transformer) axis. The latter sets up the armature torque current by transformer action. When the armature turns, its conductors cut the field axis flux and generate an armature speed emf which sets up a second magnetizing component of armature current which induces the machine cemf in the transformer axis of the stator. It has an elliptical revolving field which tends to become circular at synchronism. Runaway speed is low, often not greatly above synchronism. Speed control is accomplished by adjusting voltage or series resistor or by shifting brushes. This last also permits reversing the direction of rotation.

Probable Future Trends. These include stronger magnetic materials, conducting materials with lower resistivity, and insulating materials which are usable at higher temperatures.

MUSICAL SOUND

Musical sound may be characterized as an aural sensation caused by the rapid periodic motion of a sonorous body while noise is that due to non-periodic motions. The above statement, originally made by Helmholtz, may be modified slightly so that the frequencies of vibration of the body fall into the limits of hearing: 20 to 20,000 cps. This definition is not clear cut; there are some noises in the note of a harp (the twang) as well as a recognizable note in the squeak of a shoe. In other cases it is even more difficult to make a distinction between music and noise. In some modern "electronic music" hisses and thumps are considered a part of the music. White noise is a complex sound whose frequency components are so closely spaced and so numerous that the sound ceases to have pitch. The loudness of these components is approximately the same over the whole audible range, and the noise has a hissing sound. Pink noise has its lower frequency components relatively louder than the high frequency components.

The attributes of musical sound and their subjective correlates are described briefly. The number of cycles per second, frequency, is a physical entity and may be measured objectively. Pitch, however, is a psychological phenomenon and needs a human subject to perceive it. In general, as the frequency of a sonorous body is raised, the pitch is higher. However, pitch and frequency do not bear a simple linear relationship. To show the relationship, a pitch scale can be constructed so that one note can be judged to be two times the pitch of another and so on. The unit of pitch is called the mel, and a pitch of 1000 mels is arbitrarily assigned to a frequency of 1000 cps. In general, it is observed that the pitch is slightly less than the frequency at frequencies higher than 1000 cycles, and slightly more than the frequency at frequencies less than 1000 cps. Pitch also depends on loudness. For a 200 cycle tone if the loudness is increased the pitch decreases, and the same happens for frequencies up to 1000 cps. Between 1000 and 3000 cps pitch is relatively independent of loudness, while above 4000 cps, increasing the loudness raises the pitch. A rapid variation in pitch when the variation occurs at the rate of from two to five times per second is called vibrato. The pitch variation in mels may be large or small but the rate at which the pitch is varied is rarely greater than five times per second. Violinists produce vibrato by sliding their fingers back and forth a minute distance on a stopped string. A variation in loudness occurring at the rate of two to five times a second is called tremolo. Singers

often produce a combination of tremolo and vibrato to give added color to their renditions.

Like frequency, intensity is a physical entity defined as the amount of sound energy passing through unit area per second in a direction perpendicular to the area. It is proportional to the square of the sound pressure, the latter being the rms pressure over and above the constant mean atmospheric pressure. Since sound pressure is proportional to the amplitude of a longitudinal sound wave (see WAVE MOTION) and to the frequency of the wave, intensity is proportional to the square of the amplitude and the square of the frequency. Sound intensity is measured in watts per second per square centimeter and, since the ear is so sensitive to sound, a more usual unit is microwatt per second per square centimeter. By way of example, a soft speaking voice produces an intensity of .1 microwatt/cm² sec, while fifteen hundred bass voices singing fortissimo at a distance 1 cm away produce 40 watts/cm² sec. Because of such large ranges of intensities, the decibel scale of intensity is normally used to designate intensity levels. An arbitrary level of 10⁻¹⁶ watts/cm² sec is taken as a standard for comparison at 1000 cps. This is very close to the threshold of audibility. At this frequency, other sound levels are compared by forming the logarithm of the ratio of the desired sound to this arbitrary one. Thus $\log I/10^{-16}$ is the number of bels a sound of intensity I has, compared to this level. Since this unit is inconveniently large, it has been subdivided into the decibel one-tenth its size; $10 \log I/10^{-16}$ equals the number of decibels (db) the sound has. A few intensity decibel levels are listed:

	db
Quiet whisper	10
Ordinary conversation	60
Noisy factory	90
Thunder (loud)	110
Pain threshold	120

While intensity levels can be measured physically, loudness levels are subjective and need human subjects for their evaluation. The unit of loudness is the phon, and an arbitrary level of zero phons is the loudness of a 1000-cps note which has an intensity level of 0 db. Sounds of equal loudness, however, do not have the same intensity levels for different frequencies. From a series of experiments involving human subjects, Fletcher and Munson in 1933 constructed a set of equal loudness contours for different frequencies of pure tones. These show that for quiet sounds (a level of 5 phons) the intensity level at 1000 cycles is about 5 db lower than an equally loud sound at 2000 cycles, for 30 cycles about 70 db lower, and at 10,000 cycles about 20 db lower. In general, as the intensity level increases, loudness levels tend to be more alike at all frequencies. This means that as a sound gets less intense at all frequencies, the ear tends to hear the higher and lower portions of sound less loudly than the middle portions. Some high fidelity systems incorporate circuitry that automatically boost the

high and low frequencies as the intensity level of the sound is decreased. This control is usually designated a loudness control.

That entity which enables a person to recognize the difference between equally loud tones of the same pitch coming from different musical instruments is called timbre, quality, or tone color. A simple fundamental law in acoustics states that the ear recognizes only those sounds due to simple harmonic motions (see VIBRATION) as pure tones. A tuning fork of frequency f , when struck, causes the air to vibrate in a manner which is very nearly simple harmonic. The sound that is heard does, in fact, give the impression that it is simple and produces a pure tone of a single pitch. If one now strikes simultaneously a series of tuning forks having frequencies f (the fundamental), $2f$, $3f$, $4f$, $5f$, etc. (overtones), the pitch heard is the same as that of the single fork of frequency f except that the sound has a different quality. The quality of the sound of the series can be changed by altering the loudness of the individual forks from zero loudness to any given loudness. Another way to alter the tone quality is to vary the time it takes for a composite sound to grow and to decay. A slow growth of an envelope even though it contains the same frequencies makes for a different tone quality than one which has a rapid growth. The difference in quality between a b-flat saxophone and an oboe is almost entirely due to the difference in growth or decay time.

A fundamental theorem discovered by the mathematician Fourier states that any complicated periodic vibration may be analyzed into a set of components which has simple harmonic vibrations of single frequencies. If this method of analysis is applied to the composite tones of musical instruments, it is seen that these tones consist of a fundamental plus a series of overtones, the intensity of the overtones being different for instruments of differing timbre. Rise and decay

times will also differ. The reverse of analysis is the synthesis of a musical sound. Helmholtz was able to synthesize sound by combining sets of oscillating tuning forks of various loudness to produce a single composite steady tone of a definite timbre. Modern synthesizers are more sophisticated. Electrical oscillators of the simple harmonic variety are combined electrically and then these electrical composite envelopes are electronically modified to produce differing rise and decay times. A transducer changes the electrical composite envelope into an acoustical one so that a sound of any desired timbre rise and decay time can be produced. An alternate way to produce similar effects is to use an oscillation known as the square wave. When this is analyzed by the method of Fourier, it is shown to consist of a fundamental plus the odd harmonics or overtones. Another kind of oscillator, a sawtooth wave, when analyzed, is shown to consist of the fundamental and all harmonics—even and odd. A square wave or a sawtooth wave produced by an appropriate electrical oscillator can be passed through an electrical filter which can attenuate any range of frequencies of the original wave. This altered wave can later be transformed into the corresponding sound wave. In this way sounds having a desired rise and decay time, plus the required fundamental and overtone structure, can be made as desired.

N

NEUTRINO

The neutrino is an elementary particle postulated by W. Pauli¹ in 1930 to explain the apparent non-conservation of energy and momentum in that class of nuclear radioactivity known as beta decay. A quantitative theory of beta decay incorporating the neutrino hypothesis was formulated by E. Fermi² in 1933 in analogy with the quantum theory of radiation and served to predict the nature of the neutrino and its extremely weak interaction with matter. According to the Pauli-Fermi ideas, the neutrino (in Italian, "little neutral one") is a particle of vanishingly small and possibly zero rest mass, no electrical charge, with spin 1/2, and the ability to carry energy and linear and angular momentum. Its interaction with matter is so weak that a 3-MeV antineutrino is predicted to be capable of penetrating an astronomical thickness of matter, e.g., 100 light-years of liquid hydrogen. In 1956, a group of Los Alamos physicists³ succeeded in making a direct observation of the neutrino, $\bar{\nu}_e$, emitted from beta-decaying fission fragments produced in a powerful reactor at the Savannah River Plant operated by the du Pont Company for the U.S. Atomic Energy Commission. These investigators used giant liquid scintillation detectors to observe the inverse beta decay reaction

$$\bar{\nu}_e + p \rightarrow e^+ + n$$

where p is the target proton and e^+ and n are the product positron and neutron. The experiment consisted of observing the distinctive delayed coincidence between the prompt annihilation of the positron and the capture of the neutron by a cadmium isotope dissolved in the scintillator. In 1957, following the "overthrow" of parity conservation in weak interactions as a result of the work of Lee and Yang⁴, the character of the neutrino was further elucidated. Two kinds of neutrinos were accepted: the neutrino, ν_e , produced in beta decay in association with positrons, and the antineutrino, $\bar{\nu}_e$, produced in beta decay in association with negative electrons. The neutrino emerged as completely polarized with the spin angular momentum parallel (antiparallel) to the linear momentum for the antineutrino (neutrino). A theory of weak interactions encompassing the neutrino, in which the relativistically invariant forms, vector and axial vector,

were found to be sufficient to account for most of the known characteristics of the weak interactions, was then formulated by Marshak and Sudarshan⁵, and Feynman and Gell-Mann⁶.

In 1962, an experiment at the Brookhaven National Laboratory by a Columbia-Brookhaven group⁷, using a heavily shielded 10-ton spark chamber array, showed that the neutrino most frequently associated with the decay of the π meson differed from the neutrino produced in nuclear beta decay, thus enlarging the class of neutrinos to four: ν_e , $\bar{\nu}_e$, ν_μ , $\bar{\nu}_\mu$. It now appears that any decay or inverse process involving an electron has associated with it an electron type neutrino while any such process involving a mu meson occurs in association with a mu-type neutrino. It was suggested at the 1964 International High Energy Conference in Dubna that these neutrinos be distinguished by the names muneutrino and elneutrino.

A search with high-energy machines⁸ for a particle which may be responsible for the weak interaction and which decays into a muneutrino and a muon or an elneutrino and an electron shows that, if it exists, it is more massive than 1.8 protons. Neutrino physics now encompasses low-energy reactions using fission reactors, work in the structure of the weak interaction using giant electronuclear machines, and the beginnings of various studies of natural neutrino sources such as the sun and high-energy cosmic rays.⁹

NEUTRON

Discovery. The discovery of the neutron by Chadwick¹ in 1932 represented a great step forward in the investigation of nuclei of atoms. Chadwick found that a radiation emitted when α -rays from polonium reacted with beryllium could project protons from a thin sheet of paraffin wax. Although the radiation itself produced no observable ionization when passing through a gas, the protons released from the paraffin were detected in an ionization chamber. Inability to produce ionization was interpreted as a lack of electric charge. From measurements of the ionization from the protons, Chadwick deduced that the so-called beryllium radiation must consist of neutral particles with a mass very nearly equal to that of the proton. He announced the discovery of the neutron, a previously unknown particle. It has been confirmed that the neutron has no charge and a mass of 1.008982 atomic mass units. Thus it is heavier than the proton by 0.00139 mass unit. The introduction of the neutron into nuclear structure produced a sharp change in the previously held ideas. Lacking knowledge of the neutron, masses of atomic nuclei had been attributed solely to protons. The number of protons required on this basis for most nuclei greatly exceeded the known charge number. In an attempt to solve this dilemma, a number of electrons were assigned to each nucleus to adjust the charge number to the proper value. This compromise created an even greater problem, that of accommodating so many electrons in the small space occupied by a nucleus. Bringing the neutron into the picture, it is now only necessary that a nucleus contain protons to equal the charge number with the rest of the mass contributed by neutrons. No electrons are required.

Detection. Because it is a neutral particle the neutron can be detected only by means of a secondary charged particle which it releases in passing through matter or by means of the radioactivity which the neutron can induce in stable elements. Protons may be projected by collisions with neutrons in hydrogenous material and the ionization from the protons can be measured in an ionization chamber, as in the original experiment with neutrons. Secondary charged particles may be the direct result of nuclear disintegration produced by neutrons, as in the case of the reaction $B^{10} + n^1 \rightarrow Li^7 + \alpha$.

Commonly the radioactivity induced in stable elements by neutron capture serves to detect neutrons, and this technique is known as the activated foil method. Also fission may be utilized for detection of neutrons by placing fissionable material inside an ionization chamber and observing the ionization generated by the fission fragments.

Decay. The neutron in the free state undergoes radioactive decay. Elaborate experiments by Robson² were required to identify the products of the decay and to measure the half-life of the neutron. He showed that the neutron emits a β -particle and becomes a proton. The half-life was found to be 12.8 minutes. In stable nuclei, neutrons are stable. In radioactive nuclei, decaying by β -emission, the neutrons decay with a half-life characteristic of the nuclei of which they are a part.

Energies. The kinetic energy of neutrons has an important bearing on the behavior of neutrons when interacting with nuclei. These kinetic energies may range from near zero to as much as 50 MeV. It is, therefore, natural to classify neutrons in terms of energy according to their properties in each range of energy. For example, energies from zero to about 1000 eV are usually called slow neutrons. Because they are more readily captured by nuclei than faster neutrons, slow neutrons are responsible for a large number of nuclear transformations. When slow neutrons have velocities in equilibrium with the velocities of thermal agitation of the molecules of the medium in which they are situated, they are called thermal neutrons. The distribution of these velocities approaches the Maxwell distribution

$$dn(v) = Av^2 e^{-\frac{Mv^2}{2kT}} dv$$

where v is the neutron velocity, M its mass, k is Boltzmann's constant and T the absolute temperature. In the slow neutron range of energies, various atomic nuclei show strong absorption (capture) of neutrons at fairly well-defined energies. Neutrons having energies corresponding to those of the absorption bands are called resonance neutrons. Frequently, neutrons with energies greater than 1000 eV and less than 0.5 MeV are termed intermediate neutrons. In more general terms, all neutrons with energies greater than 0.5 MeV are called fast neutrons. The practical upper limit of neutron energy is set by the devices so far developed for accelerating charged particles to extremely high energies.

Magnetic Moment and Spin. Alvarez and Bloch³ succeeded in measuring the moment of the magnetic dipole associated with the known spin of 1/2 possessed by the neutron. More refined measurements by Cohen, Corngold, and Ramsey⁴ of the magnetic moment μ_n yielded a value of

$$\mu_n = -1.913148 \text{ nuclear magnetons}$$

Interactions with Nuclei. Neutrons may be scattered or captured by heavy nuclei. Scattering

may be elastic, resulting only in the change of direction of the neutrons, or inelastic in which the neutron loses part of its energy to the scattering nucleus. Collisions with light nuclei, in absence of capture, result in communicating considerable fractions of the neutron energy to the target nucleus. A neutron colliding head-on with a proton will give practically all its kinetic energy to the proton. As the mass of the target nucleus increases, the transfer of energy decreases, in accordance with the laws of conservation of energy and momentum. The loss of energy by mechanical impact is utilized in slowing down fast neutrons, a process known as moderation. Slow neutrons are more useful, for example, in the production of radioelements from stable elements by neutron capture. A good moderator should have low mass and a small capture cross section. The rate r of capture of neutrons from a neutron flux F (neutrons $\text{cm}^{-2} \text{sec}^{-1}$) incident on a layer of matter having N nuclei per square centimeter is given by

$$r = F\sigma N$$

where σ is the complete probability of capture. Replacing r by dN/dt and writing the flux as nv , where n is the number and v is the velocity of the neutrons, we have

$$\frac{dN}{dt} = -nv\sigma N$$

which integrated gives

$$N = N_0 e^{-nv\sigma t}$$

where N is the number of unchanged nuclei in the target area at time t and N_0 is this number at time $t = 0$. The cross section σ is so named because it has the dimensions of an area. The unit for the cross section is the barn equal to 10^{-24}cm^2 . When, as is often the case, σ is proportional to $1/v$, the advantage of slow neutrons in capture interactions becomes apparent. When the value of σ departs sharply from that predicted by the $1/v$ law, it usually increases over a narrow range of energies, and we have what is called a RESONANCE. Slow neutron cross sections are customarily quoted for thermal neutrons at 20°C, corresponding to a value of v of 2200 m/sec. In Table I values of σ are given for a few representative stable elements.

Additional interactions of neutrons with nuclei include the release of charged particles by neutron-induced nuclear disintegration. Commonly known reactions are $n-p$, $n-d$, and $n-\alpha$. In these cases, the incident neutrons may contribute part of their kinetic energy to the target nucleus to effect the disintegration. Hence, more than mere neutron capture is involved. Then there is usually a lower threshold for the neutron energy below which the reaction fails to occur. Another important reaction involving neutrons is fission which may occur under different conditions for either slow or fast neutrons with appropriate fissionable material.

TABLE I. THERMAL NEUTRON CAPTURE CROSS SECTIONS*
 $v = 2200 \text{m/sec}$

Element	σ (barns)
Boron	759
Cobalt	38
Cadmium	2 450
Gadolinium	46 000
Gold	99.8
Helium	0
Lead	0.170
Oxygen	<0.0002

* See reference 5 for data for other elements.

Sources of Neutrons. Any nuclear reaction in which neutrons are released might serve as a source of neutrons. In the initial experiments on neutrons, an $\alpha-n$ reaction was used. Because of the charge on the α -particle, it must have a high kinetic energy to penetrate a nucleus. Thus polonium α -particles could release neutrons from beryllium. Such a natural source produces relatively few neutrons. The yield of neutrons from charged particle reactions can be increased manyfold by the use of particle accelerators. Here large numbers of charged particles of high energy can be used in the bombardment of the target to release numerous neutrons. Frequently deuterons or protons are used for the bombardment. A far more prolific source is the nuclear reactor. Fission of uranium is usually the source of the neutrons in this case. A nuclear reactor, as usually constructed, generates neutrons of different energies in various parts of its structure. Neutrons of suitable energy for a given experiment may be brought outside the reactor through channels into appropriate sections of the reactor.

Structure of the Neutron. Ordinarily the neutron is regarded simply as a particle which is a component of nuclei and which can exist only briefly in the free state. For many purposes this view is sufficient. However, it has become obvious from experiments, for example, in very high-energy accelerators, that the neutron must have a complex structure. This view is reinforced by the nature of the decay of the neutron. A β -particle is ejected from the neutron on decay, but it is quite certain that the electron did not exist within the neutron prior to the decay. Rearrangements of an internal structure of the neutron must provide the energy for the formation and ejection of the β -particle. One theory would have the neutron consist of a proton and a π^- meson bound together so that they oscillate between a completely bound state and a more loosely bound state. Such a theory might also explain the feeble interaction which has been observed between electrons and neutrons at very short range. At present, it may be sufficient to say that the neutron must have a complex

internal structure of a nature at present not very clearly understood.

Additional information on the neutron may be obtained from the books listed below.^{6,7}

NEUTRON ACTIVATION ANALYSIS

Neutron activation analysis is a method of elemental analysis based upon the quantitative detection of radioactive species produced in samples via nuclear reactions resulting from neutron bombardment of the samples.

Types of Neutron Reactions. The neutron-induced reactions are of two main types: (1) those induced by very slow (thermal) neutrons, having energies of about 0.025 eV, and (2) those induced by fast neutrons, those having energies in the range of MeV.

All stable isotopes are capable of capturing thermal neutrons, but with characteristic reaction cross sections which vary widely from isotope to isotope, even of the same element. Promptly following the capture of a thermal neutron by a stable nucleus, the compound nucleus de-excites itself by the emission of one or more "prompt" gamma-ray photons. If the resulting product nucleus is a radioisotope, its later decay can be detected and can be of use in the activation analysis detection of that element. Thermal-neutron capture reactions are therefore referred to as " (n, γ) " reactions. For example, in the determination of vanadium, with thermal neutrons, some of the V^{51} stable nuclei present in the sample to be analyzed undergo the $V^{51}(n, \gamma)V^{52}$ reaction. Vanadium-52 is radioactive, decaying with a half-life of 3.77 minutes, emitting a β^- particle and a 1.43-MeV gamma-ray photon.

Fast neutrons predominantly interact with nuclei by means of (n, p) , (n, α) , $(n, 2n)$, and (n, n') reactions. Whereas the thermal-neutron capture reaction forms an isotope of the original element, but now one mass unit higher, the $(n, 2n)$ fast-neutron reaction forms an isotope of the same

element one mass unit lower. An example of this type of reaction is the $N^{14}(n, 2n)N^{13}$ reaction. Nitrogen-14 is the abundant stable isotope of nitrogen, whereas N^{13} is radioactive, decaying with a half-life of 10.0 minutes by positron emission. The (n, n') fast-neutron type of reaction, termed a "neutron inelastic scattering" reaction, forms an excited state (nuclear isomer) of the original nucleus, with unchanged mass number (A), but a measurable half-life. The $Se^{77}(n, n')Se^{77m}$ reaction is a good example of this type of reaction. Selenium-77 is one of the stable isotopes of selenium, whereas Se^{77m} is a radioactive isomer of Se^{77} that decays with a half-life of 17.5 seconds, emitting an isomeric-transition 0.16 MeV gamma-ray photon. In (n, p) reactions, the product nucleus has the same mass number as the original nucleus, but is a different element, namely, lower by one unit in atomic number (Z). A widely utilized reaction of this type is the $O^{16}(n, p)N^{16}$ reaction. Oxygen-16 is the principal stable isotope of oxygen; N^{16} is a radioactive isotope of nitrogen, decaying with a half-life of 7.35 seconds, emitting exceptionally high-energy beta particles and gamma-ray photons. In (n, α) reactions, the product nucleus has a mass number 3 units lower than the original nucleus, and a Z that is 2 units lower than originally. For example, in the fast-neutron detection of phosphorus, the $P^{31}(n, \alpha)Al^{28}$ reaction is often utilized. Normal phosphorus consists entirely of P^{31} ; Al^{28} is a radioactive isotope of aluminum, decaying with a half-life of 2.27 minutes, emitting a β^- particle and a 1.78-MeV gamma-ray photon in each disintegration.

Theory of the Method. When a sample containing N nuclei of a given type (a particular Z and A) is exposed to a flux ϕ of neutrons, resulting in a particular nuclear reaction having a cross section σ , the rate of formation of product nuclei by this reaction, in nuclei per second, is simply $N\phi\sigma$. The units of ϕ and σ are neutrons per square centimeter per second and square centimeters per nucleus, respectively. If the product nucleus is a radioactive species, some of these nuclei will be decaying while the irradiation is going on. If the irradiation of the sample with neutrons is continued for a long time, compared with the half-life of the radioisotope formed, a steady state, or "saturation" condition will be reached, in which previously formed nuclei are decaying at the same rate that new ones are being formed, thus with no further increase in the disintegration rate of this particular product with continued irradiation at that flux. Therefore, the saturation activity of a given species, at zero decay time (i.e., just at the conclusion of the irradiation), is $A_0(\text{satn}) = N\phi\sigma$.

At intermediate irradiation times (t_i), the activity of a particular induced species (A_0 , expressed in disintegrations per second, i.e., dps) is equal to $N\phi\sigma S$, where S is a "saturation" term that is equal to $1 - e^{-0.693t_i/t_{0.5}}$, where $t_{0.5}$ is the half-life of the radioactive species. The saturation term is dimensionless and ranges only from 0 (at $t_i = 0$) to 1 (at $t_i = \infty$). It rapidly approaches

a value of one, asymptotically, acquiring values of 1/2, 3/4, 7/8, 15/16, . . . at $t_1/t_{0.5}$ values of 1, 2, 3, 4, Because of this rapid approach of S to its maximum value, it is pointless to activate a sample for a period of time longer than a few half-lives of the radioactive species of interest. Longer irradiation merely generates more interfering activities of longer half-lives.

In the basic activation equation, σ is the isotopic cross section for the particular type of nuclear reaction, for neutrons of a specified energy. It assumes that the neutron flux, and energy, are constant throughout the sample. The N term is itself equal to $wfaN_A/AW$, in which w is the weight of the sample (in grams), f is the weight fraction of the element in the sample, a is the fractional abundance of the target stable isotope among all the stable isotopes of the element, N_A is Avogadro's number, and AW is the ordinary chemical atomic weight of the element. In actual analyses, of course, either f or the product wf is the unknown quantity.

Neutron Sources. In neutron activation analysis work, the most widely used neutron sources are (1) research-type nuclear reactors, and (2) small accelerators. Modern research reactors are mostly of the pool type and operate at power levels of 10 to 1000 kW, providing thermal-neutron fluxes of 10^{11} to 10^{13} n cm⁻² sec⁻¹ and fission spectrum fast-neutron fluxes of about the same magnitude. The small accelerators used in neutron activation analysis work are largely low-voltage (100 to 200 kV) Cockcroft-Walton deuteron accelerators, capable of producing up to about 10^{11} 14-MeV neutrons/sec from a tritium target (with a 1-mA deuteron beam current), via the $H^3(d,n)He^4$ reaction. Samples of typical size (~ 1 cm³) can thus be exposed to a 14-MeV neutron flux of about 10^9 n cm⁻² sec⁻¹. In a moderator, these can produce a thermal-neutron flux of the order of 10^8 n cm⁻² sec⁻¹. Unfortunately, at full-power operation, the lifetime of the tritium target is only of the order of an hour to a few hours. Some work is carried out also with lower-energy neutrons generated by the $Be^9(d,n)Be^{10}$ reaction with a 2-MeV positive-ion Van de Graaff accelerator, or by the $Be^9(x,n)Be^8$ reaction with bremsstrahlung produced by a 3-MeV electron Van de Graaff accelerator. These produce thermal-neutron fluxes in the range of 10^8 to 10^9 n cm⁻² sec⁻¹. Isotopic sources, such as Po^{210} -Be, Pu^{239} -Be, and Am^{241} -Be, also generate neutrons, but the maximum thermal-neutron flux attainable with such sources is only about 10^5 n cm⁻² sec⁻¹. They are useful for teaching purposes, but not for real analytical work.

Sensitivities for Various Elements. As the available neutron flux increases, the level of induced activity per unit mass of an element also increases; hence, the sensitivity of detection is higher, i.e., the limit of detection is lower. With a nuclear-reactor thermal-neutron flux of 10^{13} n cm⁻² sec⁻¹, a maximum t_1 of one hour, and reasonable counting efficiencies, it is found that the median limit of detection for some 70 elements is about 10^{-3} μ g. A few of these elements can be detected

down as low as 10^{-7} μ g; a few only to about 10 μ g. The method, with such high neutron fluxes is the most sensitive known method for over half the elements of the periodic system. With 1-gram samples, the μ g absolute sensitivities correspond to parts-per-million (ppm) concentration sensitivities. Samples ranging from minute samples up to 10 grams or somewhat more can be irradiated and analyzed. With longer irradiation periods, the detection limits for about half of the 70 elements (those forming longer-lived induced activities) can be reduced further. The most sensitively detected elements (limits $\leq 10^{-3}$ μ g) are the following: Ag, As, Au, Br, Co, Cu, Dy, Er, Eu, Ga, Ge, Ho, I, In, Ir, La, Lu, Mn, Na, Nb, Pd, Pr, Re, Rh, Sb, Sm, Sr, U, V, W, and Yb. Some elements are more sensitively determined by activation with fast neutrons than with thermal neutrons.

At the lower (10^8 to 10^9) thermal-neutron fluxes attainable with the small accelerators, the limits of detection are of course 10^4 to 10^5 times higher than for the reactor 10^{13} flux. At a 10^9 thermal-neutron flux, the sensitivities for the same 70 elements thus range from 10^{-3} μ g to 0.1 gram, with a median of 10 μ g. With a 14-MeV neutron flux of 10^9 n cm⁻² sec⁻¹, a number of additional elements can be detected fairly sensitively, down to levels of 0.1 to 10 μ g, e.g., N, O, F, Si, P, Cr, and Fe.

Forms of the Method. In practical analytical work, one does not employ the basic activation analysis equation ($A_0 = N\phi\sigma S$), per se, but instead uses a comparator technique. When samples are to be analyzed for one or more elements, standard samples of these elements are activated at the same time as the unknowns and then are counted in an identical manner (counting efficiency ϵ). When the counting data are corrected to the same decay time, then, A (unknown)/ A (standard) grams element in unknown/grams element in standard, since ϵ , f , AW , ϕ , σ , and S are the same for both unknown and standard. In the equation, A refers to the counting rate (rather than disintegration rate) of the radioisotope formed by the element in question—in unknown and standard, respectively. Not only is the comparison technique simpler, but it removes any dependence upon literature values of σ , and experimental values of ϵ and ϕ , which often are not accurately known. At levels well above the limits of detection, careful application of this comparison technique results in precisions and absolute accuracies in the range of ± 1 to 3 per cent of the value.

The method is employed in two different forms: the purely instrumental form and the radiochemical separation form. The instrumental form is fast and nondestructive, and is based upon the quantitative detection of induced gamma-ray emitters by means of multichannel gamma-ray spectrometry. It is the preferred method where it applies. Induced activities are identified by the energies of their gamma-ray photopeaks observed in the NaI(Tl) scintillation counter pulse-height spectrum of the activated samples. The amount

of the element present in a sample is computed usually from the photopeak (total absorption peak) height or area of its gamma ray, or one of its principal gamma rays, compared with that of the standard.

Where interferences from other induced activities are very serious, and cannot be removed adequately by decay, spectrum subtraction, or computer solution, one must turn to the radiochemical separation form of the method. Here the activated sample is put into solution and equilibrated chemically with measured amounts (typically 10 mg) of added carrier of each of the elements of interest, before chemical separations are carried out. The element to be detected needs then to be recovered in chemically, and radiochemically, pure form, but it need not be quantitatively recovered, since the carrier recovery is measured and the counting data are then normalized to 100 per cent recovery. This form of the method is slower, but it applies to pure beta emitters, as well as to gamma emitters, and it does eliminate interfering activities. It is free of the usual complications of microconcentration analysis: high blanks from reagent impurity, and losses by adsorption and coprecipitation.

Neutron activation analysis is now a well-established method of elemental analysis, carried out in many laboratories and utilized by many more through available commercial activation analysis services. It is now widely applied in almost every branch of science, engineering, and medicine, where either its great sensitivity (at high fluxes) or its speed (with the instrumental form of the method), or both, are used to advantage.

NEUTRON DIFFRACTION

An experiment by Laue, Friedrich and Knipping in 1912 demonstrated that x-rays were a form of electromagnetic radiation, with a wavelength of the same order of magnitude as the distance apart (10^{-8} cm) of atoms in crystals. This meant that beams of x-rays could be diffracted by crystals in a rather similar way to that in which an optical diffraction grating, in which the elements are separated by about 10^{-3} cm, will produce a spectrum for visible light. As a result of Laue's discovery, a technique for studying the underlying structure of solids by "x-ray diffraction" has grown up. For any given solid, the end product of this technique is a specification of the shape and content of the building block, or "unit cell," out of which the solid is built. The content is specified in terms of "electron density," and it follows that the various atoms or ions which make up the molecule of the substance can be identified.

A rather similar, but in some respects a much more powerful, technique has grown up using beams of neutrons instead of x-rays. A neutron is often thought of simply as a particle, with a mass approximately equal to that of a hydrogen atom, but in terms of wave mechanics a beam of neutrons can be regarded as a wave motion. If the neutrons are moving with velocity v , then they can be considered to have a wavelength equal to h/mv , where m is the mass of the neutron and h is Planck's constant. If such a neutron beam is scattered by a solid, it will be distributed in space as if it were radiation of this wavelength. It so happens that for neutrons having energies equivalent to a temperature of a few hundred degrees centigrade, which are readily obtainable from nuclear reactors, the wavelength is about 10^{-8} cm, i.e., 1 \AA , which, as we have seen above, is about equal to the interatomic distance in solids. It was shown in 1936 that neutrons, then obtainable only from a radium-beryllium source, could indeed be diffracted by solids. However, it is only since nuclear reactors have produced intense beams of suitable neutrons that the application of diffraction techniques to the study of solids has proved worthwhile.

Since high-intensity neutron beams are only available at a limited number of research institutions throughout the world, we shall be concerned only with their application to problems which cannot be solved by any other method. In particular, we shall enquire what can be achieved with neutrons which cannot be found out by

using a beam of x-rays, and we shall see the answers to this question by making a comparison of the ways in which atoms and solids scatter x-rays and neutrons. *X-rays* are scattered by the outer, extranuclear, electrons in an atom, and it is for this reason that x-ray diffraction studies produce a picture of electron density. It follows that heavy atoms, such as lead and uranium which contain many electrons, will predominate in these pictures and that a one-electron atom, i.e., hydrogen, can be located and detailed with much less accuracy. On the other hand, *neutrons* are scattered not by electrons but by the nucleus of an atom, and the way in which the scattering power increases with the mass of the atom is very far from being a steadily increasing function. The scattering power or, more precisely, what we call the "scattering length" arises from the summation of two quite separate effects. The first of these depends on the size of the nucleus, which has a radius proportional to the cube-root of the atomic weight, so that this effect does indeed increase with atomic weight, but nevertheless fairly slowly. Superimposed on this scattering, however, is resonance scattering, which depends in a complicated way on the actual structure of the nucleus and on its energy levels. This additional scattering often varies quite considerably from atom to atom, and sometimes from isotope to isotope, as we advance up the periodic table. When we combine together the two effects, and thus assess the resultant scattering by a nucleus, we find that it varies quite irregularly from atom to atom and this is illustrated for elements at the lower end of the periodic

system in Fig. 1. It will, however, be noted that there is a relatively small spread of values among these scattering lengths. The mean value for all the nuclei which have so far been measured is 0.62×10^{-12} cm, and practically all elements have values which lie between a half and twice this average. As a result of this we find that most elements are roughly equally "visible" to neutrons, though there are a few very interesting exceptions. The practical outcome of this is that hydrogen atoms can be located quite accurately in whatever environment they are found, and this has meant important advances in our knowledge of the role of hydrogen bonds and molecules of water of crystallization in building up the structures of both inorganic and organic crystals. At the same time, we have often been able to get much improved information on the thermal motion of molecules, particularly in those common cases where hydrogen atoms are found on the outside of molecules and which, therefore, provide a very good index of the molecular movement. The technique of detection becomes much more powerful if we can use *deuterated* material, instead of ordinary hydrogen. Deuterium has a neutron scattering length of 0.65×10^{-12} cm and is, therefore, a "good average" atom, whereas ordinary hydrogen, at 0.38×10^{-12} cm, is somewhat below average. This comparison provides a very good example of a difference between the scattering behavior of two different isotopes of an element, arising from differences in the nuclear structures.

Another important field of chemistry to which neutron diffraction has contributed some useful

FIG. 1. The variation of the nuclear scattering amplitude of elements for neutrons, shown as a function of atomic weight, in units of 10^{-12} cm.

results is in the study of the compounds of uranium, and post-uranic elements, with nitrogen and oxygen. In the case of x-ray studies, the 92 electrons of a uranium atom completely overshadow the seven and eight of nitrogen and oxygen respectively. For neutrons, however, the value of the scattering length for uranium (0.85×10^{-12} cm) is actually less than the value for nitrogen (0.94×10^{-12} cm) and is only fractionally greater than that of oxygen (0.58×10^{-12} cm).

So far we have been considering the process whereby the neutron is scattered by the atomic nucleus, and this is a process which occurs for all atoms. There is, however, an additional scattering which takes place for *magnetic* atoms, i.e., for atoms which have a resultant magnetic moment on account of the fact that the atoms contain unpaired electrons. Examples of this are an atom of iron in metallic iron, which appears to contain 2.2 unpaired electrons, and the doubly-charged manganese ion Mn^{++} , which contains 5 unpaired electrons, in manganese salts. Such atoms or ions scatter additional neutrons, making an additional contribution to the scattering length by an amount which is proportional to the magnetic moment. If the magnetic moments in such a material are not arranged in any regular single direction, but point haphazardly as in a *paramagnetic* material, then there will not be any well-defined diffracted beams but there will be a broadly distributed contribution to the scattered background. This contribution may be a little difficult to identify but, nevertheless, the identification can be achieved and the phenomenon can be confirmed. In other magnetic materials, however, all the magnetic moments in a single domain lie parallel to a single direction, and in the particular case of a *ferromagnetic* material they all point *algebraically* in the same sense. In this circumstance the magnetically scattered neutrons contribute specifically to the diffracted beams and the intensity of these is observed to vary with increase of temperature, falling to a minimum at the approach of the Curie temperature, above which no ferromagnetic alignment takes place. In the case of antiferromagnetic materials, in which the moments lie parallel to a single direction but alternately up and down with opposite algebraic sense, the neutron data are extremely informative. In such a material it will be appreciated that, from a *magnetic* point of view, the repeat distance (considering the alternate $+$ and $-$ moments) is twice the repeat distance which is apparent when only the *chemical* nature of the atoms is considered. This means that extra diffraction spectra will be produced at smaller angles of scattering, corresponding to what would happen if the inter-line spacing of an optical diffraction grating was doubled. The existence of antiferromagnetism can, therefore, be detected very directly by noting the appearance of these extra spectra, particularly if the neutron diffraction pattern is compared with either an x-ray pattern or with a neutron pattern taken at a higher temperature at which the regular magnetic

arrangement has broken down. Such a comparison of results obtained at two different temperatures is illustrated in Fig. 2. Results such as these have established the antiferromagnetic structures of a variety of materials and have demonstrated the true nature of ferrimagnetism, as for example in the ferrites in which moments are directed in both positive and negative directions but with a net balance in one direction.

FIG. 2. A comparison of neutron diffraction patterns taken at 4 and 420 K for an antiferromagnetic alloy, $Au_2Mn_{17}Al_{13}$. At the lower temperature, intense magnetic lines A and B appear, but at the higher temperature, where very little magnetic order remains, these extra lines have practically disappeared. The patterns also show the composite nature of the nuclear scattering line C at low temperature, which occurs because the crystal symmetry changes from cubic to tetragonal when the magnetic order becomes established.

Moreover, with further research, it has been demonstrated that these structures are only the simplest examples of a wide range of "magnetic architecture" which it is now possible to draw in detail as a result of study with neutron beams. This later work, devoted to the iron group of transition elements and the elements of the rare earth group, has identified a variety of non-collinear arrangements of magnetic moments such as the spiral spins in $MnAu_2$, the umbrella structure in CrSe, composite structures in holmium and erbium and the complicated structures,

not yet fully understood, which occur in metallic chromium.

In our discussion so far, we have implicitly assumed that when a neutron is scattered by an atom it is scattered *elastically* and does not lose any of its energy. This is no more than a first approximation to the truth, because atoms are by no means rigidly fixed but are in vibration about their mean positions because of their possession of thermal energy. A neutron which makes collision with an atom may, therefore, lose or gain a quantity of energy. If we keep in mind the fact that atoms in a solid are not isolated, and that the movement of one atom will invariably affect to some degree the motion of its neighbors, it becomes fruitful to regard the interchange of energy as occurring between the neutron and the lattice vibrations of the solid. Indeed we speak of "phonons" which are the embodiment in *particle* form, from the point of view of wave mechanics, of the quanta of energy among the crystal vibrations. If we could measure accurately the interchanges of energy, then we could learn about, and indeed study in detail, the phonon spectra and the dispersion law for the solid. In fact, for *neutron* scattering, but not for x-rays, such a measurement can be made and this gives a quite unique value to the use of inelastic neutron scattering for studying solids. The particular supremacy of neutrons becomes clear if we consider the actual energies of a neutron and x-ray quantum which possess the same wavelength. We find in fact that the latter is roughly 10^5 times larger. Thus, whereas the energy of a neutron of wavelength 1 \AA is about equal to that of a quantum of crystal energy yet the energy of a 1 \AA x-ray is 10^5 times greater. It follows, therefore, that if a neutron gains or loses such a quantum, then its own energy will be greatly changed; for example, it could easily be roughly doubled or halved. On the other hand such an interchange for an x-ray would be quite insignificant and the resulting change of wavelength could not be detected. It is in fact possible, therefore, to measure both momentum and energy changes in neutron-phonon interchanges, and this information leads directly to the details of the dispersion law in the solid.

As the intensity of the beams of neutrons available from research reactors steadily increases, with roughly a ten fold increase each ten years, these techniques become progressively more powerful and determinative, leading to a steadily widening view of solids and liquids in the several unique respects which we have discussed. The limitations in the use of these techniques are those set by the limited availability of suitable nuclear reactors, and it may be fairly said that many promising applications have not yet been tested.

NOISE, ACOUSTICAL

Strictly defined, noise is any unwanted sound, whether pleasant or unpleasant. More commonly, however, sounds that are unpleasant and disturbing, or that mask desired sound, are termed noise. Thus, noise, in a general sense, may be thought of as any sonic disturbance. Depending upon the degree of pitch distribution, intensity, and persistence, noise can range from being merely annoying, to hazardous or injurious. In our highly industrialized society, with its rapid growth of energy-producing and converting systems, noise has become a major problem. Some of its harmful effects are interference with mental and skilled work, impairment of sleep, creation of emotional disturbances, damage to hearing and a deterioration of health and well-being. Consequently, the control and reduction of noise has become an important science.

Adequate measuring means are a prime requirement in the scientific control and reduction of noise. Even then, the problem of establishing a true relationship between the subjective and objective properties of noise is difficult because of the many different aspects of human reaction to noise. The first relationship between the subjective and objective measurement of sound is the simplified rule relating *loudness in sones* to the *loudness level in phons*. The loudness scale in sones is proportional to the average person's estimate of the loudness. Thus, the loudness level, P , of a given sound, in phons, is numerically equal to the median sound pressure level, p_L , of a free progressive wave at a frequency of 1000 cps presented to listeners facing the source, which is judged by the listeners to be equally loud. The sound pressure level, p_L , is defined as

$$p_L = 20 \log_{10} \frac{p}{p_0} \text{ (decibels)} \quad (1)$$

where p is measured sound pressure, in microbars, and $p_0 = 2 \cdot 10^{-4}$ microbars.

The relation between sones, S , and phons, P , is given by

$$S = 2^{(P-40)/10} \quad (2)$$

Referring to Eq. (2), a loudness level of 40 phons produces a loudness of one sone, and a loudness level of 80 phons produces a loudness level of sixteen sones, etc.

The simplest means for the measurement of noise is the sound level meter, an instrument comprising a microphone, an amplifier, frequency weighting networks, and an output meter. The characteristics of the frequency weighting networks in the meter are based upon the equal loudness contours of hearing for different levels.

More sophisticated means for measuring noise include octave band and one-third octave band sound analyzers that supply information on the sound level in various frequency ranges. These analyzers are used for research on the reduction of machine noise, transmission and other areas where information on the sound levels in specific frequency bands is required. Narrow-band analyzers may be used to obtain the spectrum of a noise. The sound-pressure spectrum level is that level within a frequency band of 1 cps. This level is plotted against frequency to obtain the spectrum frequency characteristic of the noise. If the spectrum level of a noise is known, sophisticated means may be used to relate the objective to the subjective qualities of the noise.

As noted earlier, noise abatement has become an important science. For instance intensive research on the quieting of automobiles has been in progress for three decades, with outstanding results; some of the major problems remaining to be solved involve wind- and road-induced noise. Similarly, research has been carried out on the reduction of noise of all types of household appliances employing motors, fans, compressors,

pumps, gears, and other moving parts. Another phase of acoustical engineering involves methods for reducing the transmission of sound through the walls, floors, ceiling and partitions in all manner of buildings or enclosure by the use of construction and materials based on fundamental acoustical principles.

The noise in typical environments and noise produced by various sources are given in Table 1.

The masking effect produced by noise reduces the intelligibility of speech. For example, if the speaker and listener are separated by 5 feet, the levels of noise that will barely permit reliable word intelligibility are 51 db for normal conversation, 57 db for raised speech, 63 db for very loud speech, and 69 db for shouting.

A person subjected to high noise levels for long periods of time may suffer considerable impairment of hearing. The use of ear protectors may provide sufficient insulation under such conditions.

The establishment of any scale of noisiness judgment is difficult because human response and reaction are very complicated. However, for random noise a relationship between the objective and subjective responses may be outlined in a general form as shown in Table 2.

TABLE 2. RELATION BETWEEN OBJECTIVE AND SUBJECTIVE RESPONSES TO NOISE

Sound Pressure Level (db)	Noise Evaluation
40-50	Quiet
70-80	Moderate
80-90	Noisy
90-100	Very noisy

NUCLEAR INSTRUMENTS

Nuclear instruments are those devices which are used to make the group of measurements which is commonly described as nuclear radiation detection. These measurements are understood to encompass not only the indication of the presence of nuclear radiation but also the determination of the amount, energy, and related properties. The nuclear instrument may be considered to consist of two parts, a detector and a measuring apparatus. The interaction of the radiation with the instrument takes place in the detector, while the measuring apparatus takes the output of the

detector and performs the required analysis to accomplish the measurement.

Nuclear instruments are either pulse type or non-pulse type. In the pulse-type instrument, the output of the detector is a series of signals separated or resolved in time, each signal representing the interaction of a nuclear particle with the detector. If the pulse feature of the detector output is used, e.g., in counting particles or in measurement of the distribution in energy of particles the nuclear instrument is said to be pulse type.

In the non-pulse type of operation of a nuclear system, no attempt is made to resolve the signals of individual particles. Instead, the average effect due to many interactions of the radiation with the detector is measured directly. This type of instrument, which can be described as a mean-level type detection system, is typified by the current-type ionization system. The current output is proportional to the number of particles incident upon the detector per unit time.

For the study of the physics of the interaction of NUCLEAR RADIATION with the detectors, it is convenient to divide the numerous forms of radiation into classes, based on the mode of interaction with matter as in a detector, and to discuss the properties of a prototype of each class. The radiations which are convenient as prototypes are protons, electrons, fission fragments, gamma rays, and neutrons.

The prototype protons, fission products, electrons, and all other radiations consisting of charged particles each interact with matter primarily by the production of excitation and ionization of the matter through which it is passing, with ionization playing the major role. The nuclear particles lose energy at a rate w per ion pair formed. Values of w for particles passing through gases range from 25 to 50 eV per ion pair. The three types of particles differ primarily in their penetrating ability; for example, a 0.03-MeV electron will pass through a 2.2 mg/cm² of air, while a proton would need 0.9 MeV of energy and a fission product 64 MeV to penetrate the same thickness.

Gamma rays and neutrons, being uncharged radiations, differ in their primary mode of interaction from the types discussed above. However, both gamma rays and neutrons undergo primary interactions with matter which produce secondary charged particles that interact with the detector, thereby producing effects which make possible the detection as in the case of the radiation types which consist of charged particles. The interaction of gamma rays with matter produces secondary electrons through the principal mechanisms of photoelectric effect (see PHOTO-ELECTRICITY), Compton scattering and pair production, as well as through several other secondary mechanisms.

In the case of neutrons, there are also several mechanisms by which the interaction with matter takes place, each of which is the basis for a potential method of detection. The most useful ones are: (1) neutron-induced transmutations in

which the product particles make detection possible; examples are (n, α) , (n, p) , (n, γ) , and $(n, \text{fission})$ reactions; (2) neutron-induced transmutations, leading to radioactive nuclei, the subsequent decay of which makes the detection possible; (3) elastic scattering of neutrons (for example, by a proton) in which the recoil proton can be detected.

Several nuclear radiation detectors depend for their operation on the IONIZATION that is produced in them by the passage of charged particles. This group of detectors includes ionization chambers, proportional counters, Geiger-Müller counters, semiconductor-radiation detectors, cloud chambers, and spark chambers. For the uncharged particles, such as neutrons and gamma rays, the charged particles which are required for the production of ionization originate by the secondary processes referred to above.

In other detectors, excitation and sometimes molecular dissociation also play important roles. These phenomena, in combination with ionization, bring about the LUMINESCENCE in scintillation detectors and the latent images in photographic emulsions. Also, molecular dissociation is important in chemical detection systems, i.e., those devices that function through the occurrence of certain chemical reactions.

One of the oldest, but still most widely used, types of detector employs a gas-filled chamber. Depending on the mode of operation of this chamber, the detector type is known either as an ionization chamber, a proportional counter, or a Geiger-Müller (G-M) tube. The principles of operation and the differences in the three modes of operation can be explained by the use of Fig. 1 and 2. The system shown in Fig. 1 consists of a gas-filled chamber containing a central electrode that is well insulated from the chamber wall. A potential V is applied between the central electrode and the chamber wall through the high resistance R shunted by the capacitor C_2 .

FIG. 1. Schematic diagram for pulse operation of gas-filled chamber. (Reprinted from Price, W. J., "Nuclear Radiation Detection," p. 42, New York, McGraw-Hill Book Company, Inc., 1964).

Assume that the passage of a nuclear particle releases N_1 ion pairs within the chamber. The positive and negative charges within the chamber move toward the chamber wall and central electrode, respectively, because of the direction of the electric field. Under the condition that

Fig. 2. Pulse-height vs applied-voltage curves to illustrate ionization, proportional, and Geiger-Müller regions of operation. [Reprinted from Montgomery, C. G., and Montgomery, D. D., *J. Franklin Inst.*, 231, 449 (1941)]

the time constant RC_2 is much greater than the time required for the collection of the charge, the charge Q appearing on the capacitor per particle as a function of V is given by curve 1 in Fig. 2. For a particle producing a larger number of ion pairs N_2 , curve 2 is obtained.

These curves can be divided into four main regions. In region I there is a competition between the loss of ion pairs by recombination and the removal of charge by collection on the electrodes. With increasing field, the drift velocity of the ions increases; therefore the time available for recombination decreases, and the fraction of the charge which is collected becomes larger.

In region II the recombination loss is negligible, and the charge collected is

$$Q_1 = N_1 e \text{ and } Q_2 = N_2 e$$

The change in voltage across the capacitor C_2 is

$$\Delta V_1 = \frac{N_1 e}{C} \quad \text{and} \quad \Delta V_2 = \frac{N_2 e}{C}$$

where C is the sum of the ionization-chamber capacity and C_2 . This region is referred to as the saturation region or the ionization-chamber region.

In region III the collected charge is increased by a factor M through the phenomenon of gas multiplication. The electrons which are released in the primary ionization are accelerated sufficiently to produce additional ionization and thus

add to the collected charge. At the onset of region III, the multiplication M for a given applied voltage is independent of the initial ionization, thus preserving the proportionality of pulse sizes. This strict proportionality breaks down with increase in applied voltage until, at the upper limit of region III, the pulse size is independent of the initial ionization. This region, in which gas multiplication is employed while at the same time a dependence of the collected charge on the initial ionization remains, is known commonly as the proportional region. The upper end of it is designated as the region of limited proportionality.

In region IV the charge collected is independent of the ionization initiating it. Rather, gas multiplication increases the charge to a value that is limited by the characteristics of the chamber and the external circuit. This region is known as the G-M region.

Ionization chambers find wide-scale use in non-pulse-type applications, for example, in monitoring of radiation for personnel protection. Pulse-type operation is not attractive in the ionization chamber region because of the relatively small-size pulse released by an individual nuclear particle. On the other hand, in the proportional region, gas multiplication increases the size of pulses while at the same time information concerning the size of the initial ionization is maintained. Therefore, proportional counters are useful as counting devices (with the ability to discriminate between particles making different amounts of ionization) and for energy measurements. Geiger-Müller counters are widely used for counting electrons between particles and gamma rays inasmuch as the large discharge pulse is triggered by the very small ionization which these particles produce. However, they have no capability for differentiating between radiation types or for measuring the energy of the particles which trigger the discharge.

Inasmuch as Lord Rutherford utilized light scintillations in his famous alpha-scattering experiments, the scintillation detector is one of the oldest methods of nuclear radiation detection. However, the modern scintillation detector, a device of great utility, only evolved after the development of special photomultiplier tubes for the purpose. Figure 3 shows the schematic of a modern scintillation detector for counting. When charged particles pass through certain substances, ionized and/or excited states are produced, which, during their return to the normal states, produce light flashes, or scintillations. By coupling the scintillators with a photomultiplier tube, a pulse of charge can be passed to an electronic system, as shown in Fig. 3, thus making counting possible. Also, if the electronic counter is replaced by electronic equipment for measuring the pulse size, the scintillation detector is very useful for energy measurements.

Various scintillators are available including crystals of inorganic and organic materials, liquids, powders, plastics, glasses, and gases. Therefore, the designer has available a wide range

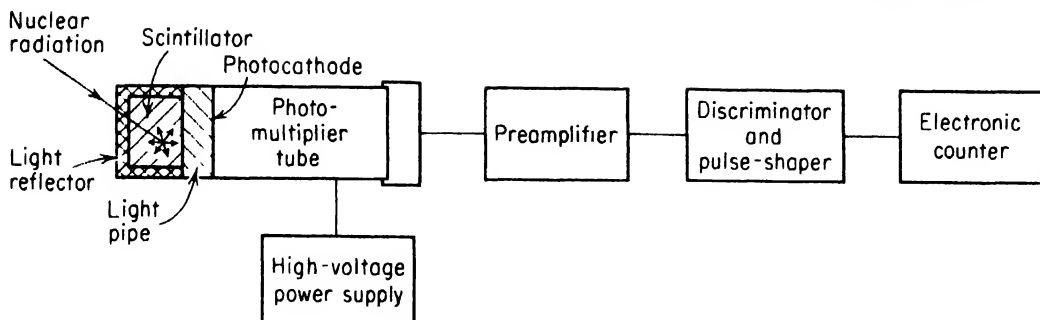

FIG. 3. Schematic diagram of a scintillation detector (Reprinted from Price, W. J., "Nuclear Radiation Detection, p. 160, New York, McGraw-Hill Book Company, Inc., 1964)

of sizes, shapes, and compositions, and consequently can optimize conditions for a wide variety of measurement problems including a wide range of radiation types and energies. In addition, the time duration of the pulse produced can be much shorter than those in the gas-filled chambers, and the density of the detection medium is usually much higher. As a result of these several advantages, there is a large group of applications in which the scintillation detectors have superiority over gas-filled chambers as well as over other detectors. Gamma-ray spectroscopy is an outstanding example of an important class of measurement made possible by the scintillation detectors.

The newest of the important nuclear radiation detectors is commonly referred to as the semiconductor radiation detector, after the fact that it is the properties of semiconductor materials that make these detectors possible. In this detector an electric field is set up across a semiconducting medium of low electrical conductivity. Usually the low conductivity region is the charge-depletion region in a semiconductor diode operated at reverse bias. When a charged particle passes through the semiconductor, electron-hole pairs are produced in it. The charges are caused to separate by the electric field, and the resulting electrical signal can be transmitted to the electronic measuring system to give important information concerning the particle detected.

The semiconductor radiation detector has several key properties, the combination of which accounts for the rapid rise of importance of this detector type. These properties include linearity of pulse height vs energy, very rapid response time, high resolution, convenient dimensions, thin windows, insensitivity to magnetic fields, variable sensitivity with respect to particle energy, relative insensitivity to gammas and neutrons, and relatively low cost. For example, the availability of semiconductor radiation detectors has revolutionized the spectrometry of charged particles.

Several other types of detectors are in use and are quite important in specialized measurements. These other detectors include nuclear-track plates, cloud chambers, spark chambers, Cerenkov counters, chemical detectors, calorimetric

methods and various special types of neutron detectors. For details on the principles of operations and the characteristics of these detectors, as well as more information on the three detector types described above, the reader is referred to the textbook "Nuclear Radiation Detection", by W. J. Price (New York, McGraw-Hill Book Co., Inc., 1964) and the references included in that book.

WILLIAM J. PRICE

NUCLEAR RADIATION

Nuclear radiation results from the transitions of atomic nuclei. The two chief types of transition in natural radioactivity are those in which the number of constituent particles of a given nucleus (nuclide) are changed by the emission of one or more particles, and those in which there is a rearrangement of the particles of a given nuclide, without change in number, such that the nuclide passes from a state of higher energy to a state of lower energy.

Soon after the discovery of radioactivity in 1896, it was found that naturally radioactive substances emit three kinds of radiation: alpha (α), beta (β) and gamma (γ) rays. The first two consist of high-speed charged particles, alpha and beta particles respectively. They are called *particle* rays to distinguish them from the gamma rays discovered by Villard in 1900. The latter were shown by a series of experiments to be a form of high-frequency electromagnetic radiation traveling with the speed of light. However, in discussing the nature of these rays, it must be remembered that experiments clearly show that the so-called *particles* may exhibit distinctly *wave-like* characteristics, and conversely the higher the frequency of the gamma radiation the more pronounced becomes the *particle-like* character of its individual quanta or photons. From such considerations springs present-day quantum mechanical theory.

Two of the most important differences between alpha rays and beta rays are: (1) they are deflected in opposite directions by a magnetic field indicating that they are oppositely charged, and (2) the alpha particle is far more massive than the beta particle. Early measurements indicated that alpha particles may be emitted with speeds up to $1/15$ the speed c of light, and beta rays with speeds up to $0.96c$. The rest masses of the two particles and their energy equivalents in millions of electron volts (MeV) are

$$M_{\alpha}(\text{alpha particle}) = 6.645 \times 10^{-27} \text{ kg} = \\ = 3727.2 \text{ MeV}$$

$$m_{\beta}(\text{beta particle}) = 9.109 \times 10^{-31} \text{ kg} = \\ = 0.511 \text{ MeV}$$

Thus the alpha particle is nearly 7300 times more massive than the beta particle. The reason for such a difference in the masses was found early in this century. In experiments begun in 1903, Rutherford showed that an alpha particle is the doubly charged (positive) nucleus of a helium atom. Experiments of Becquerel and others identified the beta particle as the then recently discovered, negatively charged electron.

With the discovery of what has been called "artificial" or induced radioactivity by Irene Curie and her husband Frederick Joliot in 1933, it was found that positive electron (positron) emission may occur in nuclides whose instability results from the nucleus possessing "too much charge for its mass." This is, of course, only another form of beta emission represented as β^+ whereas ordinary electron emission is represented as β^- .

Certain characteristics of nuclear radiation such as their great penetrating power, their capacity to ionize a gas, affect a photographic plate, or produce serious or fatal burns, and the ability of alpha rays to produce scintillations in a fluorescent screen were early recognized. The exact penetrating power of a particular ray depends upon the energy with which it is emitted by the parent nucleus, but in general it may be said that alpha rays may usually be stopped by a few sheets of paper and beta rays by a few millimeters of aluminum. Alpha and beta rays, because of their particle character, have a more sharply defined range than gamma rays, and a significant fraction of the gamma radiation may pass through a number of centimeters of metal shield. This is because particles lose speed and kinetic energy in both ionizing and non-ionizing collisions with other particles, whereas a gamma-ray photon always travels at the same speed, and the beam of photons is usually weakened by some process such as scattering or absorption of photons. The frequencies of photons may also be reduced by the so-called *Compton collisions* (see COMPTON EFFECT).

One of the most important characteristics of alpha and beta rays is their capacity to produce ions in a gas and render it conducting. In normal air, an alpha ray will produce between 20,000

and 70,000 ion pairs per centimeter of path, depending on the speed of the ray, with maximum ionization being reached near the end of the path. A beta ray on the other hand may only produce 200 ion pairs or less per centimeter. Thus such rays lose energy rapidly in passing through a gas, and rays of a particular type and energy have a rather sharply defined range (see IONIZATION).

The range of alpha particles in air at 76 cm mercury pressure (15°C) varies from 2.7 cm for alpha particles from uranium to 8.62 cm for alpha particles from thorium C' (Po^{212}). The former are emitted with energies of 4.2 MeV while the latter, the most energetic of any from a naturally radioactive substance, are emitted with energies of 8.6 MeV.

In 1929, Rosenblum discovered the fine structure of alpha rays. That is, alpha rays from a single type of nuclide may not all have exactly the same energy and range but often consist of two or more groups with slightly different but sharply defined ranges and consequently different initial energies. This led to the ultimate recognition of the existence of different energy levels in the nucleus and is one of the most important properties of alpha rays in sharp contrast with the nature and behavior of beta rays. Along with the discovery of nuclear energy levels came recognition of the origin of gamma radiation. After the emission of an alpha (or a beta) particle, if the nucleus is left in an excited state of higher energy than the lowest or ground state, gamma radiation occurs as the result of a transition to a lower-energy state.

Beta rays have ranges in air at 76 cm mercury pressure (15°C) varying from a fraction of a centimeter for those of a few thousand volts energy to more than 400 cm for those of energies of 1 MeV. However, the beta rays from a single type of nuclide have a wide distribution of ranges and energies, the distribution being approximately continuous up to a certain maximum for the particular type of nuclide. The lack of a characteristic disintegration energy and range for the various beta particles from a given type of nuclide results from the nature of the emission process as first explained by Fermi in 1934. When a beta particle is emitted, it is necessary that at least one other particle (a NEUTRINO) also be emitted in order to conserve angular momentum of spin. Conservation of energy then demands that any energy this neutrino possesses must subtract from the energy that might have been carried off by the beta particle in the process of emission from some sharply defined energy level in the nucleus. Only the maximum possible or "end-point" energy of a given beta-ray emission curve is therefore significant for that particular nuclide. On the other hand, gamma rays result from the return of a nuclide from a higher-energy state of excitation to a lower state, or to the ground state, and have sharply defined values characteristic of the states of that nuclide. Different groups of beta rays having different end-point energies may originate from the same type of nuclide and represent different nuclear energy levels.

The experimental detection of the neutrino (and antineutrino) in the years following 1956 confirms the main aspects of the Fermi theory, and adds another particle and antiparticle, albeit of zero mass and zero charge, to those types which may be ejected from the atomic nucleus. *Nuclear radiation* may involve all of these types of rays and also the neutrons and other particles resulting from occasional spontaneous fission of a nucleus or from the intense fission in a nuclear reactor.

In addition to natural and induced radioactivity and nuclear fission, many types of nuclear transformation or disintegration may occur in cosmic-ray phenomena or in bombardment of nuclei by high-energy rays. Most of the particles produced in such occurrences are themselves unstable and decay by the emission of other particles. For instance, a neutron decays to a proton by the emission of a negative electron and an anti-neutrino. A pion (π meson) may decay to a muon (μ meson) and a neutrino, and the muon may decay to an electron and two neutrinos. To complicate matters, the neutrinos and antineutrinos in the two decay processes seem to be slightly different. In a wider sense, all the nuclear particles and antiparticles emitted by any nuclear process must be included in the forms of nuclear radiation.

NUCLEAR REACTIONS

Several years after the discovery of the nucleus by scattering α -particles from gold, Rutherford and his collaborators noticed that if air were exposed to the flux of α -particles, occasionally a very penetrating particle was observed. After some nuclear detective work, this phenomenon was explained in the following way: the nitrogen nucleus and the α -particle react to produce an isotope of oxygen and an energetic proton. In the chemical notation, such a reaction may be written as $N^{14} + \alpha \rightarrow O^{17} + p$, where the superscripts are the atomic mass numbers of the elements in question.

Nuclear reactions may take place only when a target nucleus and a projectile come close enough together for the nuclear forces to take effect. The range of nuclear forces is very short, about 1.5 fermis (1 fermi = 10^{-13} cm). Since nuclei and all the massive projectiles except neutrons are charged positively, they repel each other, and if they are to be brought into sufficiently intimate contact to interact, the energy of the projectile must equal or surpass the repulsive electrostatic force. Typically, for protons on light nuclei, the energy required is 1 or 2 MeV, rising to 15 MeV for protons on very heavy, highly charged nuclei. Thus to produce nuclear reactions by the collision of charged particles, we must first accelerate one of them to an energy sufficient to overcome the electrostatic repulsive force. In all nuclear reactions, energies are usually given in million electron volts and masses in atomic mass units (amu). One MeV is the energy acquired by a particle of one electronic charge as it is accelerated by an electrical potential of one million volts. An atomic mass unit is currently defined as one-twelfth the mass of a neutral carbon-12 atom.

A nuclear reaction just as its chemical counterpart, may be exoergic (kinetic energy is liberated) or endoergic (kinetic energy is absorbed). For example, Rutherford's original reaction is endoergic, consuming 1.19 MeV which is converted into mass of the product particles according to Einstein's $E = mc^2$. In the case of endoergic reactions, energy must be supplied in the form of projectile kinetic energy to make the reaction possible.

In the course of a nuclear reaction, the projectile and the target may fuse completely, or parts of nuclear matter, neutrons, protons, or clusters of these, may be transferred from the target to the projectile or vice versa. The most common projectiles are ISOTOPES of hydrogen, protons or deuterons, and α -particles which are nuclei of helium atoms. Because of their low charge, these feel the lowest electrostatic repulsion from the target. Heavier projectiles are, however, frequently used, and these include lithium, carbon, nitrogen, and oxygen ions; a few experiments have been done with projectiles as heavy as Ar^{40} . Neutrons form a special class of projectile, since they are not charged and need not possess any large amount of energy to overcome a repulsive barrier. In fact, the slower the neutrons are, the more likely they are to interact with the target simply because they spend more time in the vicinity of each target nucleus. Nuclear reactions may also be initiated by PHOTONS (electromagnetic radiation quanta) of very high energy, greater than 5 to 10 MeV. The photons are produced as x-rays when high-energy electrons from a betatron, synchrotron, or linear accelerator impinge on a target. Since photons are not charged electrically, there is no barrier, but all photonuclear reactions are endoergic, that is they require several-million-electron-volt x-rays to take place.

Rutherford's original reaction would now be commonly written thus: $N^{14}(\alpha, p)O^{17}$. The target

nucleus comes first, the projectile and the emitted particle or particles appear in that order inside the parentheses, and the residual nucleus is last. The superscript gives the atomic mass of the isotope. Some common abbreviations are p for proton, n for neutron, d for deuteron (H^2), t for triton (H^3), γ for γ -ray.

The projectile energy range over which nuclear reactions are important varies from a fraction of an electron volt for neutrons to several hundred million electron volts per atomic mass unit for charged particles. At very high energies, the projectiles appear to interact with the individual neutrons and protons of the target rather than with the nucleus as a whole, and we leave the domain of nuclear reactions to enter the field of ELEMENTARY PARTICLE interactions.

Nuclear reactions are literally the foundation on which our world is built. The energy of the sun is nuclear in origin, deriving principally from the fusion of four protons into a helium nucleus, in the course of which 22.7 MeV are released in each fusion. The fusion is not a direct four-body reaction, but rather proceeds by stages through many two-body reactions (see SOLAR ENERGY SOURCES). Not only is our chief source of energy of nuclear origin, but the constituents of the earth are also the result of long-gone nuclear reactions, principally a series of (n, γ) processes which served to build up the elements in the earth as we now find them. One particularly pleasing success of nuclear reaction theory and experiment is the fact that the abundance of the elements and their isotopic ratios as they occur in nature can be calculated simply on the basis of the probability with which neutrons are captured by various nuclei, these probabilities having been measured in nuclear research centers.

Not only nature's energy source is of nuclear origin. The two mightiest sources of man-made energy, nuclear FISSION and nuclear FUSION, derive from nuclear reactions.

In fission, a neutron is captured by a uranium nucleus which splits (fissions) into, say, a Ba and Zr nucleus, in the process releasing about 200 MeV of energy and some neutrons which in turn split other U nuclei in the vicinity. This leads to the familiar chain reaction which, if controlled, is used to produce power by converting the fission energy (heat) into either motive power or electricity. If the chain reaction is allowed to proceed without control, a violent explosion results, i.e., an atomic bomb. We note parenthetically that what is commonly known as atomic energy should really be called nuclear energy since its source is not the entire atom, but only its nucleus. Burning of coal, on the other hand, is atomic energy, since heat is derived from the combination of a carbon atom with two oxygen atoms to form CO_2 .

Fusion as a source of energy derives from a reaction such as $H^2(d, n)He^3$ in which 3.3 MeV are released. This process is similar to the source of solar energy, in that hydrogen nuclei fuse to produce helium. It has not proved possible yet to control the nuclear fusion reaction in such

a way that it will proceed slowly. Many laboratories are currently working on this. An uncontrolled fusion reaction has, however, been achieved—it constitutes the energy source of the hydrogen bomb.

It is clear that reserves of coal and oil must someday be exhausted. When this happens, man will necessarily turn to nuclear reactions, fission, or fusion for his sources of power. At the present time, 1965, nuclear fission power plants account for only 0.6 per cent of the electricity generated in the U.S.; however, it is expected that 7 per cent of the power will be of nuclear origin by 1980, and 45 per cent by the year 2000.

The terrors of war and the blessings of abundant power both come from nuclear reactions. But that is not all. Perhaps the most significant contribution to all sciences has been the use of radioactive elements produced in nuclear reactions. Let us take a typical example. Consider the reaction $C^{13}(n, \gamma)C^{14}$. This reaction produces radioactive C^{14} which has a half-life of 5700 years. The radioactive carbon decays with the emission of an electron which can be counted with a suitable detector. Thus we are able to locate individual atoms of carbon and separate them from all others which are not radioactive. Such radioactive atoms are called tracers, and by using a variety of them, C^{13} , F^{18} , P^{32} , S^{35} , I^{131} , Au^{198} , all produced by some sort of nuclear reaction, unprecedented advances have been made in biology, chemistry, metallurgy, physiology, and medicine. Furthermore, radioactive isotopes in large amounts can be used instead of x-rays for treatment of cancer, for metallography, and for food preservation.

By means of nuclear reactions such as $Am^{241}(B^{11}, 4n)Fm^{248}$, scientists have been able to make new elements not found in nature. Some of these, for example plutonium and californium, have found important uses as reactor fuels or portable power sources. The preparation of new elements has played a decisive role in our understanding of the chemistry of heavy elements.

We turn now to a description of nuclear reactions themselves. These may be regarded as proceeding in two principal ways. First, the colliding particles may fuse, their components get thoroughly mixed in a very "hot" compound nucleus. This compound nucleus may exist in a heated state for a period varying between 10^{-16} and 10^{-20} second, a time we normally consider imponderably short, but which is nevertheless long on the nuclear time scale when compared with the transit time of a nucleon across the nucleus (10^{-22} second). The compound nucleus boils off fragments, mainly neutrons, protons, and α -particles, and in this way cools down to a normal energy content. In its final state, it is called a residual nucleus, and it may be radioactive or stable depending on the details of the reaction. If the target, the projectile, and the energy of the projectile are known, it is possible to predict what the residual nucleus will be and thus, if certain isotopes are wanted, one can tailor the reaction accordingly. We note here, however,

that the exact mechanism of these reactions is very complicated and is not really understood in a fundamental way.

In the other kind of reaction, the nuclei do not fuse, but only part of the nuclear matter is transferred from one nucleus to the other. This is often called a direct reaction, and includes stripping reactions, pickup reactions, and transfer reactions. A typical example is $\text{Al}^{27}(d, p)\text{Al}^{28}$, where a neutron is stripped from the deuteron and caught by the Al nucleus, while the remaining proton stays relatively undisturbed on its original course. The nuclei in such reactions do not come into intimate contact, and the reaction is fast, on the time scale of 10^{-22} second.

We recall now that there is at present no fundamental understanding of the nucleus, i.e., we do not know precisely how it is built up from its constituent neutrons and protons, and what the properties of the nuclear force are which holds it together (see NUCLEAR STRUCTURE). An important use of nuclear reactions is to throw light on this problem. By a careful study of nuclear reactions where all the details such as the precise energy of the projectile, the nature, energy, and angle of emission of the reaction products are measured, much insight has been gained concerning the nucleus itself. The problem is really twofold: we have to understand and be able to express mathematically the mechanism of a nuclear reaction, and then we must proceed to extract information about the participating nuclei from it. At present both aspects are only promising, so that our deeper understanding seems to await either a clear breakthrough or a painstaking development of more detailed experiments and ever more complicated theoretical calculations. The prize, however, is worth reaching for: its promise is to reveal the nature of nuclei, the smallest stable constituents of matter, and the laws which govern their interactions to give man immense power for war or for peace.

NUCLEAR REACTORS

A nuclear reactor is a facility in which nuclear fuel is assembled for the purpose of supporting a sustained, controlled, neutron-fission chain reaction.

The controlled fissioning of atoms of nuclear

fuel, resulting from interaction with neutrons, is the crucial event in a nuclear reactor. All of the manifold applications of "atomic energy," from nuclear power to atomic bombs, to radioactive isotopes, depend directly on the fissioning of fuel atoms or on the by-products therefrom. Basically, all these applications of atomic energy derive from just three consequences or by-products of fission: (1) release of heat energy, (2) release of direct radiation including neutrons, and (3) generation of "fission products," the fragments of the fissioned atoms which themselves are highly radioactive isotopic species.

Role of Neutrons. Within an assemblage of nuclear fuel, neutrons are initially obtained from spontaneous fission or from an inserted neutron source.* Some of these neutrons cause fission of fuel atoms. Each fission releases, among other radiations, two or more additional neutrons which, in turn, may either collide with other fuel atoms and cause them to fission or may suffer a variety of other fates. Whether a neutron causes fission or ends its life some other way depends on the quantity and geometrical distribution of fuel, the moderating or poisoning effects of other materials present, and many other factors. When the fuel and other components are so arranged that a given instantaneous population of neutrons can cause sufficient fissioning to produce at least an equivalent average population of neutrons at later times, the neutron-fission chain reaction is said to be "sustained." The physical facility of which such fuel arrangement is a component part is a nuclear reactor. (In earlier days, the word "pile" instead of "reactor" was frequently used. This originated from the very first nuclear reactor which consisted of a huge "pile" of graphite and uranium.)

Thus, neutrons are the lifeblood of a reactor, just as oxygen is the essential ingredient and controller of chemical combustion of coal in an ordinary furnace. By neutron interactions, the vital process of successive generations of fission in atoms of the fuel, with their attendant release of energy, is carried on. In any given assembly, at any given moment, the rate of fissioning is proportional to the average population of neutrons. When the neutron population is constant, the rate of fissioning is steady, and the power level, i.e., the rate of energy release, is also constant. If conditions are altered so the neutron population and the rate of fissioning increases or decreases, the power level or the rate of energy release of the reactor is correspondingly increased or decreased.

Purposes for which Reactors Are Built. Reactors are usually designed to make maximum use of one or another of the products of fission: heat, radiation, or fission products.

(a) *Utilization of Heat Energy.* Fissioning of

* A neutron source, for example, would be a small capsule containing a mixture of polonium and beryllium. Alphas from the radioactively decaying polonium would interact with the beryllium to yield neutrons: ${}^4\text{He}^4 + {}^9\text{Be}^9 \rightarrow {}^4\text{C}^{12} + n^1$.

1 pound of uranium releases 3.6×10^{10} Btu of heat; or the heat equivalent of 2,000,000 pounds of oil; 1 gram of fissioned uranium yields the heat equivalent of 1 megawatt-day of electricity.

When an atom fissions, most of the heat energy is released instantaneously and essentially at the point of fission. However, most of the energy of the gammas, betas and neutrons which radiate out in all directions is also transformed into heat energy in surrounding materials. Further, the delayed radiation given off by the radioactive fission products is likewise converted into heat energy. Thus, a mixture of fission products continues to generate heat for a long time after the fission events which produced them occurred.

As a source of heat energy for generation of electric power, for desalting of ocean water, for propulsion of mobile vehicles, for the driving force in endothermic chemical processes of industry, and for other similar uses, the heat from nuclear fission has countless potential applications of major dimensions.

(b) *Utilization of Radiation.* Gammas, neutrons, betas and some alphas comprise the radiation given off when an atom is fissioned. The composition of the average radiation is different from one fuel isotope to another. For example, 2.5 neutrons, on the average, are released from each U^{235} fission, while fission of Pu^{239} releases 3.0 neutrons.

The excess neutrons, beyond those needed for sustaining the chain reaction (which is just 1 per fission for maintaining a status quo fissioning rate) and the gamma radiation from fission have many and diverse uses. Some reactors are built for generation and utilization of this radiation (in which case heat may be a nuisance, or an incidental byproduct).

As examples, radiation may be used for:

(1) *Radioisotope production:* Many very useful radioisotopes are produced when excess neutrons from a reactor are captured by ordinary, non-radioactive isotopic species.

(2) *Nuclear fuel production:* Excess neutrons may also be used to convert certain "fertile" isotopic species, which are not useful as nuclear fuels, into readily fissionable nuclear fuels. For example, thorium 232, useless as a nuclear fuel, is transformed by neutron capture and subsequent radioactive decay, into uranium 233. The abundant uranium 238 is transformed by neutron capture from its natural worthless (fuel) value into the extremely valuable plutonium 239.

Thus, by using excess neutrons from nuclear reactors, the potential nuclear fuel supply of the world may be increased many times. U^{235} is the principal naturally occurring nuclear fuel. U^{238} is 140 times more plentiful. Thorium is 7 times as abundant as all the uranium.

(3) *Sterilization of food; chemical catalysts:* The vast gamma and neutron fluxes generated in fission reactors are capable of causing various changes in the physical characteristics of materials, some detrimental and some beneficial, and profound effects in living organisms, including alteration of genetic characteristics.

Foods can be sterilized, and bacteriological processes inhibited; chemical reactions can be catalyzed, and certain types of organic materials can be polymerized by exposure to radiation. The gammas rather than neutrons are principally used in such applications because neutrons may cause undesirable radioactivity in some of the materials.

(c) *Utilization of Fission Products.* Fission products removed from the spent fuel elements of reactors can be used for many purposes. For examples:

(1) Gamma radiation from fission products in bulk has been used for sterilization of food and polymerization of chemicals.

(2) Iodine 132, and various other particular species, have been isolated and used extensively in medical diagnosis and therapy.

(3) Separated, high specific activity isotopes in the multi-megacurie range have been used for radiation therapy sources, for radiography in place of x-rays, and for concentrated sources of heat. For example, Sr^{90} has been used as a concentrated source of heat for direct thermoelectric generation of electricity to be used for instruments in satellites and in remote weather stations.

On the whole, however, to date there are practical uses for only a small fraction of the fission products now being generated, and the chief present concern is for safe and economical storage or disposal of these by-products of fission.

Components of Reactors: Types of Reactors. For a controlled neutron-fission chain reaction in nuclear fuel to proceed, there must be: (1) an assemblage of fuel of appropriate quantity, dimensions and arrangements, (2) a ready means of adjusting the fissioning rate (power level) to any desired level, i.e., a control system; (3) a means of sensing and measuring the processes in progress, i.e., an instrumentation-intelligence system; (4) a means of removing heat from the fuel and disposing of or using it, i.e., a cooling system; (5) a means of protecting the environment from the direct radiation flux of escaping gammas and neutrons, i.e., shielding; (6) a confinement system for retention of the fission products; and (7) other auxiliary components.

In the following sections, some of the basic principles applicable to the functioning of these systems are briefly sketched:

(a) *The Reactor Core.* A reactor core consists of the fuel assembly, of whatever quantity, composition, physical form, dimensions and configuration are required to enable the neutron chain reaction to proceed under the conditions and for the purposes desired in any particular case. In addition, the core includes all other intermixed components, supporting members and immediately adjacent structures and materials.

Reactor fuels are metallic in elemental form but may be readily processed into various compound forms. They may be used in reactors in any of a wide variety of chemical and physical forms. No physical or chemical circumstance affects the fissioning or other nuclear characteristics of any materials.

(b) *Coolant.* When a reactor is to be operated at power levels high enough to generate substantial quantities of heat within the fuel, means must be provided for removal of this heat. Thus, in high-power reactors, fuel is customarily in the solid forms of rods, tubes or plates, having large surface area-to-mass ratios to facilitate escape of heat. Flow channels between adjacent fuel elements accommodate circulation of a fluid heat-removal coolant. In a power reactor, the coolant becomes sufficiently hot to be converted into steam (where water is the coolant) or hot enough to generate steam in the heat exchangers outside the core. The steam then drives turbines to produce electricity in the usual way. Coolants frequently used include air, CO₂, He, N₂, water, organic liquids, sodium, and sodium potassium mixtures.

(c) *Fuel Cladding.* During reactor operation as fissioning proceeds, fission products generated in the fuel tend in many instances to migrate to the surface where, by escape into the circulating coolant, they may be carried to external parts of the system and there give rise to radiation hazards. In most cases, therefore, the fuel itself is clad in a thin impervious, metallic sheath which prevents escape of the fission products. Cladding materials include aluminum, stainless steel, ceramic coatings, and various alloys of aluminum or zirconium.

(d) *Moderator.* When fission occurs, the neutrons released are of very high energy, 2 MeV or so, on the average. It so happens that such high-energy neutrons are inefficient in causing fission in commonly used fuel atoms. Slow neutrons,* however, with energies below 1 eV, have much higher fission efficiencies per collision. Therefore, for most large reactors presently being built, arrangements are made for the fission neutrons to be quickly degraded in energy to slow, thermal energies, and the fission process proceeds mainly by thermal neutron fission. Reactors in which this is the case are called thermal reactors. It is possible and, to achieve certain objectives, it is desirable for the fissioning process to be carried on by the inefficient fast neutron process. Reactors where this applies are called fast reactors.

Neutrons lose energy only, by elastic (i.e., "mechanical," non-nuclear interaction) collision with other atoms. They lose least energy per collision with heavy (e.g., uranium) atoms and most energy per collision with low mass atoms. In thermal reactors, appropriate quantities of low-mass elements such as hydrogen, deuterium, lithium, beryllium, and carbon are intermixed with the fuel to insure that the energetic fission neutrons are promptly degraded in energy, i.e., are moderated in velocity, to the thermal range. Such low mass materials are called moderators. In some cases coolants also serve as moderators.

In fast reactors, all moderating materials are carefully excluded, so the fission neutrons are

forced to collide only with heavy mass atoms and hence lose energy slowly. They eventually do cause fission or may be captured in nonfissionable atoms.

(e) *Reactor Control.* Materials which capture neutrons without subsequently undergoing nuclear fission are called poisons. All materials, even "good" nuclear fuels, are to some extent poisons. Some materials have a much higher non-fission cross section,* i.e., poisoning effect per unit quantity, than do others. Poison materials serve a very useful purpose. They provide, the one most frequently used mechanism, though there are also others, for controlling the fissioning rate or power level of the reactor. In an operating reactor, the judicious insertion or withdrawal of an appropriate quantity of poison can control the rise or fall of the neutron population, and hence the rate of fissioning can be adjusted at will.

In practice, boron or cadmium, in rod form or other suitable shape, attached to drive motors or other suitable remotely manipulated devices, is so arranged that the operator can remove or insert at will just the appropriate amount of poison to cause the neutron population originating from a fixed source to grow rapidly or slowly, remain constant or decrease slowly or rapidly. A reactor is "shut down" when sufficient poison is inserted (or other means are used) to essentially terminate the fission chain reaction.

(f) *Auxiliary Systems.* In addition to the essential components of reactors mentioned above, fuel, coolant, controls and moderator, many other components and systems are necessary for the protection of people and the utilization of the reactor. Appropriate instrumentation is needed to enable the operator to know the status of various processes, neutron flux, radiation levels, temperatures, coolant flow rates, etc. Shielding against radiation fluxes and containment mechanisms to prevent escape of radioactivity are needed for the protection of people. Machinery for collection and utilization of the heat, or to provide access to the radiation fluxes, is necessary to the intended uses of reactors.

A large nuclear reactor facility employed for the generation of electricity or for the propulsion of an oceangoing vessel is exceedingly complicated and expensive.

(g) *Reactors in Use.* Almost 500 reactors have been built, and many more are now under construction in many countries of the world. Some older experimental ones are being dismantled. It is virtually impossible to know the precise numbers in existence at any given time and the various purposes for which they are used. As of August 1964, it was reported (Third International Conference on Peaceful Uses of Atomic Energy) that reactors were being used for production of

* Neutrons in thermal, Brownian equilibrium with surrounding atoms at nominal room temperatures have energies of about 0.25 eV. Such neutrons are called thermal neutrons.

*The "cross-section" of some given nuclear event is the probability per collision that that particular event will occur. For example, an atom of a fuel which possesses a high neutron fission cross section has a high probability of fissioning when a neutron collision occurs.

electricity in various countries approximately as follows: United Kingdom, 2300 MW; United States, 1057 MW; USSR, 900 MW; Italy, 525 MW; France, 150 MW; all others, approximately 70 MW.

As an illustration of the variety and distribution of reactors, Table 1 below lists the reactors built by the United States up to 1964. Table 2 shows the listing of reactors completed as of August 1964.†

TABLE 1. REACTORS BUILT IN THE U.S. 1942* 1964

Type	No.
Experimental, test, research and training	164
Vessel propulsion reactors	52
Production reactors	14
Power reactors	16
Critical facilities	71 cells
<i>Total</i>	317

TABLE 2. REACTORS RECORDED IN COUNTRIES OTHER THAN THE U.S. TO AUGUST 1964

Country	No
Canada	7
France	25
West Germany	13

NUCLEAR STRUCTURE

The basic problem of nuclear structure was first sharply defined in 1932 when Chadwick discovered the neutron. The nucleus was then recognized to be a system of A particles (nucleons) of nearly equal mass (Z protons and $N = A - Z$ neutrons). The forces binding the "nucleons" together must be quite distinct from the well-known electromagnetic interactions which will evidently operate to push the nucleons apart, as well as gravitational forces which appear to be too weak to have any influence in the nucleus at all.

The nuclear forces are found to be of short range ($\sim 10^{-13}$ cm). Within their short radius of interaction, they become strongly attractive (depths near 100 MeV), but at very small distances the interaction becomes so powerfully repulsive that nucleons seldom come closer than about 0.4×10^{-13} cm from one another. This character of the nuclear force produces "saturation." The binding energy per nucleon is nearly constant ($\sim 8.0 \pm 1$ MeV) throughout the periodic table, while each nucleon occupies a volume which may be approximated by a sphere of radius 10^{-13} cm.

The forces described above are assumed to operate between each pair of nucleons. Their exact nature is rather complicated and depends upon the motion, and even the orientation of the nucleons. We do not as yet have a completely trustworthy expression for this force, but rapid progress is being made in this field.

Even if the nuclear force were precisely known, the structure of the nucleus would not be immediately understood in its entirety. Methods are not at present available for solving the three-body problem in closed form for simple interactions, and for more than three bodies, drastic approximations must be used to make the problems tractable. For this reason, considerable attention in physics is devoted to constructing simplified models of the nucleus. The purpose of these models is to isolate the salient characteristics of the nucleus, and thereby obtain some understanding of its behavior.

Two very general classes of nuclear models have received considerable attention. The simplest may be described as "powder models." Here it is assumed that the motion of nucleons within the nucleus is so complicated that statistical mechanics may be employed. In one version of this model, the nucleus is treated in analogy to a drop of liquid (the nuclear forces described above are qualitatively quite similar to forces between the molecules of a liquid). Such a chaotic state seems to ensue if the nucleus is highly excited, so that the nucleons have a great deal of kinetic energy. For this reason, powder models have found their greatest usefulness in describing the nucleus during a nuclear reaction, and especially in describing nuclear fission.

In the shell model (sometimes called the independent particle model), the motion of the individual nucleons is assumed to be much more simple. Each nucleon is, in fact, assigned a definite orbit within the nucleus. The resultant motion is then reminiscent of our usual picture of electrons within the atom, all revolving nearly independently of each other about the nucleus. The motivation for introducing this model into nuclear physics came from the early (1934) observation that nuclei that contained certain numbers of protons or neutrons were unusually stable and abundant. These numbers are generally referred to as magic numbers. The set we recognize today as magic are

N or $Z = 2, 6, 8, 14, 20, 28, 50, 82, \text{ and } 126$

The major details which focus attention on these numbers may be summarized as follows:

(1) *Stability and abundance.* Nuclei with N or Z magic are unusually tightly bound and correspondingly very abundant. If both N and Z are magic (${}^2\text{He}_2$, ${}^6\text{C}_6$, ${}^8\text{O}_8$, ${}^{14}\text{Si}_{14}$, ${}^{20}\text{Ca}_{20}$, ${}^{28}\text{Ni}_{28}$, and ${}^{82}\text{Pb}_{126}$), then the nucleus is even more tightly bound. The last nucleon to complete a magic number has sometimes nearly twice the binding energy of an average nucleon. Furthermore, nuclei with Z magic possess an unusually large number of stable isotopes, and nuclei with N magic have an unusually large number of stable isotones.

(2) *Neutron capture cross sections.* Nuclei with neutron number one short of a magic number have a large neutron capture cross section, while nuclei with a magic number of neutrons exhibit a small neutron capture cross section.

(3) *Islands of isomerism.* Long lived γ -active nuclear states (half-life ~ 1 second) appear just prior to the completion of a magic number.

(4) *Electric quadrupole moments.* Nuclear quadrupole moments tend to be small near magic numbers and large far from magic numbers. A nucleus with N or Z magic appears, therefore, to prefer a spherical shape.

(5) *Delayed neutron emission.* Delayed neutron emitters (e.g., ${}^{86}\text{Kr}_{51}$, ${}^{54}\text{Xe}_{34}$, and ${}^{8}\text{O}_8$) appear when N is one greater than a magic number.

The data clearly point to an interpretation of the magic numbers in terms of shell closures, analogous to the noble gases of atomic structure. Thus it appears that the nucleon-nucleon interaction somehow averages out within the nucleus so that each nucleon, to a reasonable first approximation, sees a fairly smooth potential. Such a potential should be flat near the origin (like a harmonic oscillator), and should go rapidly to zero outside the nucleus (like a square well). A suitable form which has undergone much study is the Fermi function

$$V(r) = V_0[1 + \exp(\alpha(r - a))] \quad (1)$$

In order to reproduce the magic numbers one must add a spin-orbit term:

$$f(r)\mathbf{l} \cdot \mathbf{s} \quad (2)$$

to this central potential. Here l is the orbital angular momentum of a nucleon, and s its spin. The effect of this $\mathbf{l} \cdot \mathbf{s}$ interaction is to couple the orbital and spin angular momenta so that the states with total angular momentum $j = l + \frac{1}{2}$ will be lower in energy than states with $j = l - \frac{1}{2}$. Shell closures obtained with such a potential are found to reproduce the observed magic numbers in a simple and striking manner.

The fact that the shell model works at all in nuclei is somewhat surprising since the theoretical motivation that enhances its success in atomic structure is lacking. One has no strong central field originally in nuclei, and furthermore the nucleons are much more closely packed. Consequently, collisions, which should tend to scatter a nucleon out of its orbit, should be more

frequent. It is found that the Pauli exclusion principle plays a vital role here. When such a collision occurs, the orbit into which a nucleon would tend to be scattered is actually occupied by another nucleon. This fact makes the shell model a far better first approximation than one would originally suspect.

The main effect of the nucleon-nucleon interaction is to produce the average shell model (single-particle) potential. This, of course, is not the sole effect. Many refinements are required before an adequate description of nuclei may be attained.

Consider, for example, a nucleus with just two nucleons beyond a double closed shell. One of the nucleons will go into an orbit j , and the other into an orbit j' . These two orbits may orient themselves such that the nucleus may have total angular momentum J anywhere within the range

$$|j - j'| \leq J \leq j + j' \quad (3)$$

so long as one is consistent with the Pauli exclusion principle. If one only had single-particle potentials all states of this configuration would have the same energy independent of J . To determine the level order actually observed, one must recognize that not all of the original nucleon-nucleon interaction is used up in constructing the single-particle potential. Some "residual interaction" is left over. This residual interaction will still be of the two-body type, and it will remove the degeneracy between states of the same configuration.

The most important feature of the residual interaction is that it produces a pairing force for like orbitals (i.e., $j = j'$). If $j = j'$, and we have like nucleons, the interaction is by far the strongest if $J = 0$. This has the important consequence that for nuclei with both an even number of protons and an even number of neutrons, one must have net angular momentum equal to zero. This rule is never violated. If one adds one nucleon to this even-even nucleus, the result should be a J equal to the j of the odd nucleon. This rule is violated in only a very few cases.

There are a few nuclear phenomena which the shell model cannot describe at all. The sign of the static, nuclear, electric quadrupole moments are generally given correctly by a single-particle model, but the magnitude is frequently found to be larger than that predicted by more than a factor of ten. Similarly, electric quadrupole transition rates are frequently much faster than those given by the shell model. It seems that even in low-lying nuclear levels it is not possible to attribute all of the properties of the nucleus to the nucleons in unfilled orbits. One must take into account possible distortions of the orbits of nucleons in the closed shells.

This line of thought gives rise to the "collective model," in which the nucleons in the core (closed shells) are treated as an incompressible irrotational fluid capable of surface oscillations. Nucleons in unfilled shells will exert a centrifugal force on this fluid and tend to deform it into a

nonspherical shape. In regions of the periodic table where several shell model orbitals are nearly degenerate in energy ($90 \leq N \leq 114$ and $Z > 88$), the nuclear core takes on a rather large spheroidal deformation. The formalism of the theory is reminiscent of that for diatomic molecules. Low-lying excited states are generated through a rotation of the entire system about an axis perpendicular to the axis of symmetry. This gives rise to a band of energy levels:

$$E_J = E_0 + (\hbar^2/2I)J(J+1) \quad (4)$$

where I is a moment of inertia. The identification of spectra in nuclei which could be empirically fitted to Eq. (4) was a great triumph of the collective model.

It should be noted that I is not the moment of inertia of the entire nucleus. It is only the moment of inertia of that part of the nucleus which participates in the rotation, and this is, of course, always less than the "rigid body" value.

We note that the shell model and collective model appear to be quite different in their basic assumptions. The collective model presumes that the nucleon motions are so closely correlated that we can treat a rotation of the nucleus on the whole, while the shell model begins with independent orbitals. It is very important to remember, in this regard, that the shell-model orbitals must be properly coupled together in the nucleus. The Pauli exclusion principle must be satisfied, angular momentum must be a good quantum number, and so on. These orbitals are, therefore not so independent as it might seem. They may very well give rise to collective effects depending upon the exact way in which they are coupled together to obtain the final nuclear wave function.

Various coupling schemes have recently been examined to investigate this, but these are beyond the scope of this article. We present here a simple illustrative example. Consider a set of identical particles attracted by means of identical springs to a common origin. At time $t = 0$ each particle is at the origin and is given some arbitrary velocity. Even though each particle has a different initial velocity, and moves independently of every other particle, the system will undergo a periodic dilation and contraction due to the fact that the frequency of vibration is the same for each particle. Thus we have a collective motion exhibited by a set of independently moving particles.

NUCLEONICS

Nucleonics (nü'kli-on'iks) is a name proposed by Z. Jeffries of the Manhattan District in 1944 to describe the general field of nuclear science and technology. As popularly used, it encompasses not only the study of the atomic nucleus, but also related physical techniques, instrumentation, radiochemistry, and the applications of radioisotopes. In its strict technical sense, it refers only to the first of these and is so used here.

Prior to 1900 atoms were considered to be unalterable and indivisible entities of which the elements were composed. With the discovery of the nuclear transmutations resulting from the radioactive decay process, however, it became apparent that atoms themselves possessed internal structure.

Upon observing that in passing through matter, alpha particles were scattered through larger angles than the then current concepts of the atom would predict, Rutherford suggested that the atom actually consisted of a small, heavy, positively charged nucleus surrounded by negative charges of the same magnitude. Further observations and theoretical refinements have led to the now generally accepted concept that the nucleus also contains elementary particles, i.e., neutrons, which are electrically neutral and have a mass of 1.00897, and protons, which are positively charged and have a mass of 1.00812. Stated in simple form, then, the atom consists of a positively charged nucleus, containing neutrons and protons, surrounded by a number of negatively charged electrons sufficient to provide electrical neutrality. Although this concept of the atom has not been in serious question for almost 50 years, complete understanding of the forces which hold the neutrons and protons together has not yet been achieved.

In 1927, Aston found that experimentally measured isotopic weights differed slightly from whole numbers. From this he was led to the concept of the packing fraction, which is defined as the algebraic difference between the isotopic weight and the mass number, divided by the mass number. Although the theoretical significance of the packing fraction is difficult to assess, it does lead to some interesting conclusions with respect to nuclear stability. A negative packing fraction derives from a situation where the isotopic weight is less than the mass number, inferring that in the formation of the nucleus from its constituent particles, some mass is converted into energy. Since an equivalent amount of energy would be necessary to break up the nucleus into its constituent particles again, a negative packing fraction suggests a high order of nuclear stability. By

the same reasoning, a positive packing fraction indicates nuclear instability. Stable elements with mass numbers above about 175 and below about 25 have positive packing fractions. It is interesting to note that the packing fractions of both hydrogen and uranium are positive.

Actually, a comparison of the isotopic weight with the mass number (as is done in determining the packing fraction) is somewhat artificial. A rigorous determination of the mass-energy inter-conversion in the formation of an atom would seem to require a calculation of the difference between the sum of the masses of the constituent particles of the atom and the experimentally measured isotopic weight. The value of the mass difference thus obtained is the mass defect. The energy equivalent of this mass difference as derived from the Einstein equation yields a measure of the binding energy of the nucleus. Division of the binding energy of a nucleus by the number of nucleons (the total number of protons and neutrons) therein yields the binding energy per nucleon. In stable isotopes, the binding energy per nucleon decreases with increasing mass number, a fact which is important in nuclear fission. Secondly, the binding energy per nucleon derived in the manner described above is an average value, whereas each additional nucleon added to the nucleus has a binding energy less than those which preceded it. Thus, the most recently added nucleons are bound less tightly than those already present.

Additional considerations regarding nuclear stability may be gleaned from a consideration of the odd or even nature of the numbers of protons and neutrons in the nucleus. According to the Pauli exclusion principle, no two extranuclear electrons having an identical set of quantum numbers can occupy the same electron energy state. The application of this principle to the nucleus leads to conclusions which at least are not at variance with observations of nuclear stability. Thus, it is inferred that no two nucleons possessing an identical set of quantum numbers may occupy the same nuclear energy state. It would appear, then, that both protons and neutrons which differ only in their angular momenta or spins may exist in a nuclear state. The exclusion principle requires, therefore, that only protons having opposite spins can exist in the same state. The same consideration applies to neutrons. Accordingly, two protons and two neutrons might occupy the same nuclear energy state provided the nucleons in each pair have opposite spins. Such two-proton-two-neutron groupings are termed "closed shells," and by virtue of their proton-neutron interaction, they confer exceptional stability to nuclei which are made up of them. The nuclear forces in closed shells are said to be "saturated," which means that the nucleons therein interact strongly with each other, but weakly with those in other states. Since like particles tend to complete an energy state by pairing of opposite spins, two neutrons of opposite spin or a single neutron or proton also might exist in a particular energy state.

Any of the above conditions may be achieved when the nucleus contains an even number of both protons and neutrons, or an even number of one and an odd number of the other. Since there is an excess of neutrons over protons for all but the lowest atomic number elements, in the odd-odd situation there is a deficiency of protons necessary to complete the two-proton-two-neutron quartets. It might be expected that these could be provided by the production of protons via beta decay. As a matter of fact, there exist only four stable nuclei of odd-odd composition, whereas there are 108 such nuclei in the even-odd form and 162 in the even-even series. It will be seen that the order of stability, and presumably the binding energy per nucleon, from greatest to smallest, seems to be even-even, even-odd, odd-odd.

Although the existence of binding energies holding the nucleus together has been demonstrated, the problem of defining the nature of these forces presents itself. Clearly, repulsive electrostatic forces must exist between protons. These are "long range" in effect. To achieve nuclear stability then, compensating attractive forces also must exist. It has been concluded that "short-range" attractive forces exist between protons, neutrons, and protons and neutrons. The ($p - n$) attractive forces are considered to be of the greatest magnitude while the ($n - n$) and ($p - p$) forces are of lesser intensity, with the latter decreased by virtue of electrostatic repulsion. When the number of protons in a nucleus is greater than twenty, it is found that the ratio of neutrons to protons exceeds unity. The additional short-range attractive forces provided by the excess neutrons, therefore, may be considered as compensating for the long-range electrostatic repulsive forces between the protons. Nevertheless when the number of protons exceeds about 50, the short-range forces are insufficient to counteract the electrostatic forces completely, with the result that the binding energy per each additional nucleon decreases.

Unfortunately, the nature of the short-range attractive forces between nucleons remains essentially unresolved. An interpretation of them has been presented by Heisenberg, however, in terms of wave-mechanical exchange forces. Thus, if the basic difference between the proton and neutron in a system composed of these two particles is considered to be that the former is electrically charged while the latter is not, then the transfer of the electric charge from the proton to the neutron results in an exchange of individual identity but not a change in the system. That is to say, the system still is composed of a proton and neutron, despite the fact that the particles have exchanged their identities. Since the system itself has the same composition, it must possess the same energy after the exchange as it did before. One of the principles of wave mechanics is that if a system may be represented by two states, each of which has the same energy, then the actual state of the system is a result of the combination, i.e., resonance, of the two separate

states and is more stable than either. In the proton-neutron system under discussion, the energy difference between the "combined" state and the individual states may be considered as the "exchange energy" or "attractive force" between the particles. In an extension of Heisenberg's proposal, Yukawa has postulated that the exchange energy is carried by a new particle which has been given the name meson. Particles having the properties attributed by Yukawa to mesons have been identified in cosmic rays.

With these concepts of nuclear structure and stability, however imperfect, the process of nuclear fission of uranium can now be considered. Although fast neutrons (greater than 0.1 MeV) can cause fission in both uranium 235 and uranium 238, thermal neutrons (about 0.03 eV) are effective only with uranium 235. Uranium 238 is unsatisfactory as a fissionable material for most purposes, however, since it has a high probability for "resonance capture" of fast neutrons, which is a nonfission process. It is instructive to ponder why uranium 235 fissions with thermal neutrons and uranium 238 does not. It will be recalled that the binding energy for an even-even nucleus exceeds that for an even-odd. Consequently, the addition of a neutron to uranium 235, which yields an even-even compound nucleus, will contribute a greater binding energy than in the case of uranium 238 where an even-odd compound nucleus would be produced. Calculations yield a value of 6.81 MeV for the additional neutron in the former case, and 5.31 MeV in the latter. Using Bohr and Wheeler's calculations, it is found that the activation energy for fission is 5.2 MeV for uranium 235 and 5.9 MeV for uranium 238. Thus, the binding energy for an additional neutron in uranium 235 exceeds its fission activation energy, whereas it is less in the case of uranium 238. It can be seen then that uranium-235 fission is energetically feasible with thermal neutrons while the fissioning of uranium 238 is not.

In considering the physical forces acting in fission, use may be made of the Bohr liquid drop model of the nucleus. Here it is assumed that in its normal energy state a nucleus is spherical and has a homogeneously distributed electrical charge. Under the influence of the activation energy furnished by the incident neutron, however, oscillations are set up which tend to deform the nucleus. In the ellipsoid form, the distribution of the protons is such that they are concentrated in the areas of the two foci. The electrostatic forces, of repulsion between the protons at the opposite ends of the ellipse may then further deform the nucleus into a dumbbell shape. From this condition there can be no recovery, and fission results.

It will be recalled that the binding energy per nucleon decreases with increasing mass number. To state it differently, a greater amount of energy is released in the formation of nuclei of intermediate mass number from their constituent nucleons than is the case in nuclei of high mass number. Thus, energy is released in fission because the binding energy of the high mass number

uranium-236 compound nucleus is less than that of the intermediate mass number fission products which are produced. The total energy thus liberated in fission is about 200 MeV. Of this the kinetic energy of the fission products accounts for 160 MeV. These fragments, being of significantly lower atomic number, require fewer neutrons for stability than they actually contain immediately after fission. These excess neutrons, therefore, are "boiled off" the fission fragments, the process occurring in two distinct phases. In the first phase, "prompt" neutrons of about 2-MeV energy are released within 10^{-12} seconds after fission occurs and take up about 7 per cent of the fission energy. Subsequently, after several seconds, additional "delayed" neutrons with about 0.5-MeV energy are boiled off the fission products. These play an extremely important role in the control of the chain reaction in nuclear reactors.

Measurements made by Zinn and Szilard indicate that an average of 2.3 neutrons are released per fission. If in each fission, therefore, at least one of the released neutrons caused the fissioning of another uranium nucleus, there would result a series of fissions, i.e., a self-sustaining chain reaction. The establishment of this condition basically is dependent upon two related factors: (1) the number of neutrons which are lost by escape from the geometrical confines of the system and (2) the number which are used up in nonfission processes, such as capture by uranium 238. Loss by escape is proportional to the surface area of the system. A sphere, for example, would provide a maximum volume of fissionable material for a minimum surface area. Loss by capture may be controlled by the use of uranium suitably enriched in the 235 isotope. Thus, the quantity, quality and geometry of the system may be varied until a "critical" mass is obtained. Under these conditions, there is a constant number of neutrons in the system, that is to say, the "reproduction factor" is unity.

In order that the chain reaction might proceed under controlled conditions, certain additional features must be built into the system. Thus, the neutrons must be slowed down so that the thermal neutron uranium-235 fission process will be maximized and fast neutron uranium-238 nonfission capture will be minimized. This may be accomplished by causing the fast neutrons to undergo a series of collisions, say with carbon atoms, until their energy has been reduced below the excitation energy for the fast fission process and the threshold energy for nonfission capture. In addition, some means must be had to control the reproduction factor. The introduction of variable amounts of a strongly neutron-absorbing material, such as boron, will serve this purpose. Lastly, protection must be afforded against the lethal radiations accompanying the chain reaction.

All of the above features are incorporated in the nuclear reactor. In the typical graphite reactor, a "pile" of graphite blocks are stacked atop each other in the form of a cube. Through

each block, a hole is bored, into which the uranium fuel rods are placed. Interlaced between the graphite blocks are boron control rods whose depth of penetration into the pile may be varied. Around the whole structure a several foot thick concrete shield is poured. In operation then, the fast neutrons produced by fissioning of the uranium are thermalized in the graphite blocks. The number of thermal neutrons in the system, and hence the reproduction factor, is controlled by varying the depth of the strongly neutron-absorbing boron control rods. The radiations are absorbed in the concrete shield.

It will be recalled that the prompt neutrons are released within 10^{-12} second. Manipulation of the control rods to prevent an excessive buildup in the power level would be difficult in view of the small latitude permitted by this time interval. The delayed neutrons are emitted only after several seconds, however, and thus provide the required time for the operation of the control rod mechanism.

The graphite reactor is an example of the "heterogeneous" type reactor. In this system the fuel and the moderator (graphite) are fabricated separately in rods and blocks and stacked in a lattice form. With "homogeneous" reactors, on the other hand, the fuel and moderator are intimately mixed, as in a solution or slurry.

In the operation of a nuclear reactor, both heat and radioactive isotopes are produced. The latter may be obtained as byproducts from the processing of fuel elements to remove the fission products or by insertion of a target material in the reactor for neutron irradiation. Where the radioactive product is isotopic with the target, it usually is not possible or practical (and for most purposes not necessary) to separate the two species. If the product is not isotopic with the target, of course, chemical separation is feasible. Radioactive materials find wide use in basic and applied research, industrial applications, agricultural studies, and medical research, diagnosis, and therapy.

The large amount of heat produced in the nuclear reactor immediately suggests the possibility of using the reactor for the production of electric power. The basic change over conventional power stations involves only the replacement of the coal furnace by the reactor as a source of heat. The turbines, transmission lines, etc., would remain unaffected. Although a nuclear power station is feasible in principle, a number of technical and economic considerations present themselves. The former involve the development of suitable structural materials for the reactor and efficient heat transfer methods. In addition, the design of the reactor power station must incorporate features which will minimize the danger to surrounding communities in the event of an accident. Provision also must be made for safe disposal of the radioactive waste products (see NUCLEAR REACTORS).

In 1932, Cockcroft and Walton, using an accelerator, bombarded lithium 7 with protons and obtained helium 4. The reaction was accompanied by an energy release of 17.3 MeV

This was the first demonstration of nuclear fusion, i.e., the production of elements of higher atomic number (e.g., He) from elements of lower atomic number (e.g., H). As in the case of the fission reaction, energy is released because the binding energy of the proton is less than that of the alpha particle produced.

Unlike the fission reaction, in which there is no electrostatic repulsion to the approach of the uncharged neutron to the target nucleus, the fusion reaction requires the coalescence of two positively charged nuclei. It is clear that at least one of the reacting particles must possess exceedingly high energy to overcome this potential barrier. A temperature of about 20 million degrees centigrade is necessary to effect the reaction:

while even higher energy is required in the case of

Although the Atomic Energy Commission has not released information concerning "thermonuclear devices," discussions of them available in the open literature are of interest. Several writers have postulated that a conventional fission bomb provides the energy necessary to initiate reaction (1) and this in turn furnishes sufficient energy to trigger reaction (2). These authors believe it would not be feasible to employ a sufficiently large initial charge of tritium to make a practical device and therefore conclude that the neutron produced in reaction (1) reacts with the lithium 6 employed in reaction (2) to yield further quantities of tritium:

Assuming this to be the case, only a small initial charge of tritium would be necessary since the additional quantities produced in reaction (3) would be available to react with deuterium as per reaction (1). Thus, they envisage a type of "chain reaction" involving the sequence $1 \rightarrow 2 + 3 \rightarrow 1$. Work is in progress in several countries on a controlled thermonuclear reaction.

OHM'S LAW. See CONDUCTIVITY, ELECTRICAL.

OPTICAL INSTRUMENTS

Optical instruments are of two main types: those which project a real image, e.g., the projection lantern and the camera, and those in which the eye views a virtual image, e.g., the microscope and telescope.

The main features of optical instruments can be conveniently considered under the concepts which have been devised in their study.

Magnifying Power or Angular Magnification. This is the ratio of the angle subtended at the eye by the image to the angle subtended at the eye by the object, when the latter is in the most favorable position for observation.

Microscopes. For a normal eye, an object cannot be brought nearer than 25 cm for distinct and comfortable vision. A single converging lens, of focal length f cm, forming a virtual image at the least distance of distinct vision, has a magnifying power of $25/f + 1$. Thus a lens of focal length 2.5 cm. has a magnifying power of 11 and this is about the maximum conveniently attainable with a single lens since aberrations increase considerably as the focal length becomes shorter and a short-focus lens has to be held very close to the object (see LENS).

In the (compound) microscope a converging lens, called the objective, produces a real inverted image with a magnification of v/u , where v and u are the distances of the image and object respectively from the lens (Fig. 1). An eyepiece, acting like a magnifying glass, further magnifies this image, giving a combined magnifying power

of $v/u (25/f_2 + 1)$. The magnification produced by the objective could be made large by making v large and u small. However v is limited by the length of the microscope tube—usually 16 cm. The maximum useful magnifying power of a microscope is about 2000 because of the limited resolving power of the instrument. There is little point in increasing the size of the final image if no further detail in the object is thereby revealed (see MICROSCOPE).

Telescopes. In the case of the telescope, the object cannot normally be brought closer to the eye, and the magnifying power is the ratio of the angle subtended at the eye by the image to the angle subtended at the eye by the object. When the telescope is in normal adjustment (with the final image at infinity), the magnifying power is f_1/f_2 , where f_1 and f_2 are the focal lengths of the objective and eyepiece respectively.

If the objective of a simple astronomical telescope, consisting of two converging lenses, is illuminated with a ground glass screen and a lamp, the eye lens will form an image of the objective which can be focused on a sheet of paper. This image is known as the *exit pupil* (Fig. 2), and all rays leaving the instrument must pass through it. A metal cap with a circular hole is usually placed here in an actual instrument. The *entrance pupil* determines the amount of light which can enter the instrument and in this case it is the objective. When the telescope is in normal adjustment,

$$\text{Magnifying power} = \frac{\text{Diameter of entrance pupil}}{\text{Diameter of exit pupil}}$$

Astronomical telescopes are classified by the diameters of their objectives because this deter-

FIG. 1

FIG. 2

mines their resolving power. At night, the pupil of the eye has a diameter of about 8 mm or $\frac{1}{3}$ inch, and hence the diameter of the exit pupil of the telescope should be the same. In the case of a 6-inch telescope.

$$\text{Magnifying power} = \frac{6}{\frac{1}{3}} = 18$$

A lower power than this should not be used because the effective aperture of the objective would be reduced.

The ratio of the diameter of the objective to its focal length, known as the *relative aperture*, determines the amount of aberration in the image. If it is decided to use an $f/15$ objective, its focal length must be $6 \times 15 = 90$ inches. Hence the focal length of the eyepiece must be $90/18 = 5$ inches. Thus the focal lengths of the lenses in a telescope are controlled by the diameters of the objective and of the pupil of the eye and also by the relative aperture of the objective.

Resolving Power and Limit of Resolution. The resolving power of an instrument is its ability to reveal fine detail.

Microscopes. Abbe showed that the least distance, x , between two object points which can just be resolved by the objective of a microscope, called the limit of resolution, is given by

$$x = \frac{\lambda}{2\mu \sin \alpha}$$

where λ is the wavelength of the light used, μ is the refractive index of the medium between the object and objective, and 2α is the angle subtended by the diameter of the objective at the object points (Fig. 3); the term $\mu \sin \alpha$ is called the *numerical aperture*. When the object is in air and $\mu = 1$, since the maximum value of $\sin \alpha$ is 1, the maximum limit of resolution of the objective is $\lambda/2$. Thus two object points would just be resolvable if separated by at least half the wavelength of the light used.

For the highest resolving power the angular aperture, 2α , of the objective of a microscope must be as large as possible. Hence the object must be brought as close as possible to the front surface of the objective. This is achieved by constructing objectives of very short focal length ($2/3$, $1/6$ or $1/12$ inch).

The resolving power can also be increased by increasing the value of μ in the above formula;

FIG. 3

cedar oil is placed between the cover slip and the objective, an arrangement known as the *oil immersion objective* (Fig. 4).

FIG. 4

Yet another way of increasing the resolving power is to reduce the value of λ , and this is done in the *ultraviolet microscope* employing radiation of wavelength about half that of visible light. The resolving power is thereby doubled and the useful magnification is likewise doubled. This microscope must be combined with a camera to make the image visible.

The *reflecting microscope*, still in process of development, in which the objective is a concave mirror, also is used mainly with ultraviolet light. One of the chief advantages of the instrument is its long working distance, i.e., the distance between the object and the objective.

Electrons may be focused by electric or magnetic fields and hence may be used in a microscope instead of light. Electrons behave like waves and the wavelength is shorter the greater their speed. When accelerated under a potential

difference of 60 kV—one commonly used in *electron microscopes*—the electrons have a wavelength only 1/100,000th that of light, giving a resolving power 100,000 times greater (see ELECTRON MICROSCOPE).

Telescopes. The angle, ϕ , subtended at the objective of a telescope by two points on an object which can just be resolved, called the limit of resolution, is given by

$$\phi = \frac{1.22\lambda}{a}$$

where λ is the wavelength of the light and a is the diameter of the objective. Hence, to obtain a high resolving power, the diameter of the objective must be made as large as possible. Furthermore, the full aperture of the objective must be utilized by ensuring that the exit pupil is not greater than that of the pupil of the eye.

The Yerkes telescope, the largest refractor in the world, has an objective of diameter 40 inches. Taking $\lambda = 6 \times 10^{-5}$ cm as the average wavelength of white light,

$$\phi = \frac{1.22 \times 6 \times 10^{-5}}{40 \times 2.54} \quad (1 \text{ inch} = 2.54 \text{ cm})$$

$$= 0.15 \text{ second of arc}$$

The same expression for the limit of resolution applies to concave mirrors as well as to converging lenses. The largest concave mirror objective, at Mount Palomar, has a diameter of 200 inches, five times that of the Yerkes objective, and hence its limit of resolution is $0.15/5 = 0.03$ second of arc.

By comparison, the limit of resolution of the unaided eye is about 1 minute of arc.

Depth of Focus and Depth of Field. The greatest distance the plate of a camera can be moved without spoiling the definition of the image is called the depth of focus. The corresponding distance between the positions of the object at which it is sufficiently in focus on the plate is called the depth of the field (also called depth of focus).

If a point object at a particular distance from a camera lens is exactly focused, so that its image on the plate is a point, then another point object at a different distance from the lens will give rise to an image consisting of a blurred circular patch. Since the visual acuity of the eye

is about 1 minute of arc, the distance apart, x cm, of two points which are just distinguishable at the least distance of distinct vision, 25 cm, is given by

$$\frac{x}{25} = 1 \times \frac{\pi}{180 \times 60} \text{ radians}$$

$$x = 0.007 \text{ cm.}$$

Two circular patches, of diameters 0.007 cm, with their centers 0.007 cm apart, would, of course, just touch each other.

For contact prints, a circle of diameter 0.025 cm is taken instead of 0.007 cm, as a sufficiently small image of a point object, but this is clearly too big if the photograph is to be enlarged.

The depth of focus of a lens can be increased by reducing its aperture with a stop. In Fig. 5, the diameter of the patch of light on the plate is reduced by the stop and the image of O will be reasonably clearly focused if the diameter does not exceed 0.025 cm.

FIG. 5

The depth of focus of a microscope is approximately inversely proportional to the square of the numerical aperture. An objective of numerical aperture 1.40 has, at a magnification of 1000X, a depth of focus of only 0.0005 mm.

Field of View. The field of view of an instrument is the angle subtended at the eye by the largest object, the whole of which can just be seen. This angle, in the case of a simple telescope consisting of two converging lenses, is $a_2/(f_1 + f_2)$, (Fig. 6), where a_2 is the aperture of the eye lens and f_1 and f_2 are the focal lengths of the objective and eye lens respectively. If f_1 is doubled, thereby doubling the magnifying power, the field of view is nearly halved (f_2 is small compared with f_1).

The falling off in brightness of the edge of the image, owing to some rays from the objective failing to strike the eye lens, is called *vignetting*,

FIG. 6

and it is avoided or kept to a reasonable value by placing a circular opening, called the *field stop*, of suitable size where the image formed by the objective is situated.

Illumination in Microscopes. The final image in a microscope magnifying 1000X has an area one million times that of the object. It is therefore only one-millionth as bright, assuming no light loss in the instrument. Light is concentrated on the (transparent) object by means of a *substage condenser*.

Dark ground illumination is used for viewing tiny particles or very fine lines. The illumination is made too oblique for light to pass direct from the condenser into the objective. The objects are seen by scattered and diffracted light against a dark background.

Phase contrast illumination is a method of making the structure of transparent objects visible. The arrangement consists of an annular stop at the condenser and, beyond the objective, a phase plate consisting of a glass plate on which there is an annular layer of material to increase the optical path of the light by a quarter of a wavelength. Interference between direct and diffracted light augments the diffraction pattern of the image.

Interference microscopy is another method of making fine structure visible. The transparent object is placed between two semi-silvered surfaces and the interference between light passing through the object and light passing by it is observed.

Polarized light, obtained by a suitable polarizer below the condenser, is used in microscopes designed for geological testing of constituents in rock specimens.

OPTICAL PUMPING

The term "pompage optique" was coined by A. Kastler to describe the process of "pumping" atoms from one hyperfine quantum state to another by a process of resonant fluorescent scattering of light. The original purpose was to facilitate the detection and measurement of the radio-frequency (rf) fine and hyperfine structure, which otherwise is observable by magnetic resonance and atomic beam methods (see MAGNETIC RESONANCE, also see ATOMIC AND MOLECULAR BEAMS), yet which cannot be directly observed by optical spectroscopy, primarily because of the Doppler width of spectral lines. Optical pumping has now come to embrace any experimental work

in which fine structure, rf spectroscopic measurements, polarization of electrons or nuclei, atomic cross sections, and oscillator strengths are measured or produced by means of polarized, filtered, or modulated light, and perhaps detected by the light as well. The distinction between measurements made in this way and those of conventional spectroscopy arises from the fact that the wavelength of the light is not used to measure energy splittings.

A sample description of the process may be given in schematic form. Consider a sample of atoms in gas or vapor phase, which have a $^2S_{1/2}$ ground state. Sodium is a good example, but we ignore the nuclear spin. If exposed to the resonance radiation coupling this ground state to the $P_{3/2}$ and $P_{1/2}$ states, the atom will absorb and reemit rapidly, and if the absorbed radiation is circularly polarized, the atoms will absorb one unit ($\hbar/2\pi$) of angular momentum with respect to a fixed axis of quantization (or lose one depending on the sign of the circular polarization) as shown in Fig. 1. If the atom is not disturbed during the

FIG. 1. Absorption of circular polarized resonance radiation by a typical alkali metal.

time it is in the excited state, it will reemit any polarization, but on the average will return to the ground state with one higher (or lower) unit of angular momentum in the quantization direction. This polarization is that of the electron, but if the nucleus has a spin it is so tightly coupled to the electron spin at low fields and in the radiation process that the resulting polarization is that of the combined nucleus and electron according to the angular momentum coupling rules for $\vec{I} + \vec{J} = \vec{F}$. The polarization may be measured by disorienting the atoms by adiabatic field direction changes, or by inducing transitions between the various hyperfine or Zeeman levels and measuring the transmitted or scattered light.

If the sample vapor is mixed with a "buffer gas," which helps to prevent the diffusion of the

sample vapor out of the light beam and reduces the Doppler width of the hyperfine lines, then the atoms may be disoriented in the excited state and the pumping is reduced. However, if filtering is used, it is possible to maintain orientation effects even at several atmospheres of the buffer gas. In the example mentioned, removal of the light which couples the $S_{\frac{1}{2}}$ to the $P_{\frac{1}{2}}$ state means that the absorption probability of one of the $S_{\frac{1}{2}}$ states is reduced to zero and so equilibrium is established with the least-absorbing state most populated.

Another example will show the use of the technique in excited states. A sample such as mercury (or other Group II elements) is exposed to its resonance radiation which is linearly polarized parallel to axis of quantization. This light will cause transitions from the 1S_0 ground state to the 3P_1 $m = 0$ state. The scattered light will have the same polarization. However, if magnetic dipole transitions between the excited state levels of different m , as shown in Fig. 2, are induced by

FIG. 2. Absorption and scattering of plane polarized resonance radiation by mercury vapor when excited-state transitions are made.

rf fields, circular polarization will also be emitted and may be readily detected by a polarization analyzer. If the mercury nucleus has a spin, the ground state will also be polarized in the manner described in the first example, and the measurements are equivalent to observation of nuclear magnetic resonance in a gas, but detected by light.

A typical experimental arrangement to observe optical pumping is shown in Fig. 3. A powerful and non-noisy resonance radiation lamp is focused through polarizers and filters onto the sample cell, which may be heated to get the required vapor pressure of sample. An axis of quantization is established by a magnet, solenoid or Helmholtz coils. Transmitted or scattered light is collected and monitored by a photodetector. To facilitate detection it is often desirable to make

use of modulation techniques, similar to those used in magnetic resonance experiments (see MODULATION and MAGNETIC RESONANCE), in which the magnetic field or radio frequency is modulated, and the resulting alternating current signal synchronously detected or amplified by a phase sensitive amplifier. Because of the high efficiency in the scattering and detection process with light quanta, optical pumping signals are usually much stronger than could be obtained by direct radio-frequency or microwave absorption experiments on comparable samples.

The optical pumping of many isotopes of the Group I and II elements has been studied. It is difficult to polarize atoms in gas cells which do not have an S ground state because collisions will rapidly disorient the orbital angular momentum of the electrons, but these atoms may be studied in a beam. The process cannot be used in most cases at sample pressures higher than 10^{-3} or 10^{-4} torr, because the light will not penetrate such dense samples.

It is not possible to describe briefly a general theory of optical pumping. Each system has its own spectroscopic splitting which must be analyzed. It is usually necessary to write a "master equation" to determine the equilibrium populations in the sublevels, taking into consideration the transition probabilities into and out of these levels, and the relaxation rates. Fortunately, in most cases, all that is needed is knowledge of the relative transition probabilities, and these will probably depend only on the angular momentum quantum numbers.

One of the most effective means of extending optical orientation to other elements is by means of the spin exchange process. Outer electrons will overlap during the collision of atoms, and the spins will interchange as a consequence of a "beat" between symmetric and antisymmetric spin configurations. In the case of S -state wave functions, the coupled angular momentum is conserved, and the polarization produced by optical pumping on one atom will be thermodynamically shared with all other atoms with which a spin exchange is possible. Since outer electrons may overlap at interatomic distances much greater than a collision impact parameter, the spin exchange cross section is usually much greater than the collision cross section. Atomic hydrogen and atomic nitrogen, as well as the alkali metals, have been studied by these methods. In fact, optical orientation and spin exchange may be expected to work on ions, and the first observation of spin exchange was made with the free electron. Polarized electrons were removed by ultraviolet or discharge ionization from an optically pumped sodium vapor sample. The electrons were disoriented by rf fields, and subsequently disoriented the sodium by exchange in an observable way.

Other methods of coupling optically produced orientation also exist. Metastable (3S_1) helium atoms are long lived and may be optically pumped. The metastability is transferred with a reasonably large cross section to ground state (1S_0) atoms, and if the helium is the isotope He^3 ,

FIG. 3. Typical optical pumping apparatus: (a) resonance radiation lamp, (b) filter, (c) polarizer, (d) rf coils, (e) sample cell, (f) photodetector

the nuclear polarization is also efficiently transferred to the ground state, making it possible to produce at pressures of several torr, samples of 40 per cent polarized He^3 with relaxation times of about one hour. The contact hyperfine interaction and dipolar interactions also can transfer the angular momentum of optically oriented atoms to other atoms, but cross sections are much smaller.

Several interesting light modulation effects may be observed in pumping experiments. Light beat and modulation effects occur when an atom scatters light while it is simultaneously undergoing hyperfine transitions. If a sample is oriented in the Z direction, and a rf field excites a Zeeman resonance, the atoms will precess coherently. An additional polarized light beam passing through the sample will be modulated at the Larmor frequency. As an inverse effect, if the pumping light itself is modulated at the appropriate radio frequencies, transitions will be induced. In the example of mercury, if magnetic dipole transitions are induced in the sublevels of the (3P_1) states, the scattered light will show the beat frequency modulation of the sublevels. The varieties of these modulation effects are by no means yet exhausted.

A useful effect for studying hyperfine structure in cases where the system cannot easily be pumped is the "level-crossing" effect. Some of the levels of the fine and hyperfine structure of states of atoms more complicated than the examples described here cross one another at particular values of a perturbing magnetic field. At these points, the optical opacity of the sample to the appropriate light will be changed, and from the values of the magnetic field, and a knowledge of the general form of the hyperfine splitting, magnetic moments and hyperfine energies may be determined.

There are numerous practical applications of these methods. Optically pumped gas cell magnetometers have been made utilizing rubidium vapor or metastable helium (see MAGNETOMETRY). If modulated light is fed back to rf coils, a self-contained oscillator may be built. Rubidium and cesium gas cell ATOMIC CLOCKS have been built with stabilities of 1 part in 10^{11} . These may be made in a very simple manner, utilizing those hyperfine transitions which are not

perturbed by magnetic fields. Atomic gyroscopes may be constructed by using the optically pumped angular momentum and the light to detect precession. Perhaps the most important application has been to produce population inversion required in the operation of masers and lasers, particularly potassium and rubidium vapor, and chromium in ruby (see LASER and MASER).

OPTICS, GEOMETRICAL

The radiant energy emitted from a point of a luminous source situated in a homogeneous medium free from obstacles travels through the medium as a spherical wave front whose velocity of advance is a characteristic of the medium. A radius of this wave front is a light ray. If a ray experiences a change of medium or encounters an obstacle, it will, in general, deviate from the rectilinear path defined by the radius. The science of geometrical optics is concerned with controlled deviations.

The Law of Reflection. (a) The directions of incidence and reflection and of the normal to the reflecting surface are coplanar.

(b) The angle of reflection is equal to the angle of incidence, both angles being taken with respect to the normal (see Fig. 1(a)).

The Law of Refraction. The directions of incidence and refraction and of the normal to the refracting surface are coplanar.

FIG. 1. a-c Reflection and refraction at plane surfaces.

(b) The ratio of the sines of the angles of incidence and refraction, both angles being taken with respect to the normal, is a constant whose magnitude is a function of the properties of the two media on either side of the refracting surface (see Fig. 1(b)). The function is

$$\sin \theta_1 / \sin \theta_2 = \mu_{12}$$

The constant μ_{12} is the index of refraction for the two media when light travels from medium 1 to medium 2. If the direction of the ray is reversed, as in Fig. 1(c), it traverses exactly the same path so that

$$\sin \theta_2 / \sin \theta_1 = \mu_{21}, \quad \therefore \mu_{21} = 1/\mu_{12}$$

If the first medium is air, it is usual to drop the suffixes and to replace μ_{12} by n . If the first medium is a vacuum then μ_{12} is the absolute refractive index of the second. For air at NTP the value is 1.00028 so that, for most practical purposes the distinction between μ_{12} and n , with air as the first medium, is negligible for substances, such as glass, commonly used for light control. The value of n depends on the wavelength of the light. For

sodium yellow of 5890.6\AA , the values of n for a number of media are:

Crown glass	1.517
Flint glass	1.650
Quartz	1.544
Fused silica	1.459
Water at 20°C	1.333
Diamond	2.42

For a mathematically plane surface, the coefficient of reflection for normal incidence is dependent on the value of μ_{12} . Fresnel's law gives for this coefficient

$$\rho = [(\mu_{12} - 1)/(\mu_{12} + 1)]^2$$

Clean polished surfaces give results largely in accord with Fresnel's law. Films of grease or slight roughness appreciably reduces the value of ρ .

Total Reflection. Figure 2(a) shows a series of rays passing from air into a denser medium. Ray No. 1 experiences no deviation. The others experience progressively increasing deviations until, with the tangential ray, No. 4, the angle of

FIG. 2. Illustrating total reflections.

refraction θ_c is the greatest possible for that particular medium. Since the angle of incidence is 90°

$$1/\sin \theta_c = n, \quad \therefore \sin \theta_c = 1/n$$

By reversing the directions of the rays, we see that an angle of incidence θ_c is the maximum possible angle for emergence into the air. For angles $> \theta_c$ there is internal reflection, as in Fig. 2(b), governed by the law of reflection. The angle θ_c is called the critical angle for the particular combination of media. Figure 3 shows a number of practical applications of total reflection.

Image Formation. The geometry of Fig. 4(a) shows that the image in a plane mirror of a point in front of it is another point which lies behind the mirror along the normal from the object point, and is as far behind the mirror as the object is in front. The image of an extended object is identical in size and shape but experiences lateral inversion (see Fig. 4(b)). The image is virtual in the sense that it cannot be received on a screen.

The geometry of Fig. 4(c) shows that the image of a point in a dense medium is another point situated on the same normal to the surface and at a distance from the surface of $1/n$ of the distance of the object point. For large viewing angles, this relationship does not apply, the rays forming the envelope of a caustic as in Fig. 5(a). If the object is extended, a straight line for example, the

image is curved and concave towards the surface as in Fig. 5(b).

Refraction by Prism. Figure 6(a) shows the general case, the incident angle θ_1 being different from the emergent angle θ_1' . The deviation D is given by

$$D = \theta_1 + \theta_1' - A$$

Figure 6(b) shows the conditions for minimum deviation. $\theta_1 = \theta_2 = \theta$, say. The deviation is now given by

$$n = \sin \frac{A + D_{\min}}{2} / \sin \frac{A}{2}$$

Thus for a 60° prism for which $n = 1.517$

$$\sin \frac{A + D_{\min}}{2} = n \sin A/2 = 1.517 \times 0.5 = 0.7585$$

$$\therefore A + D_{\min} = 2 \times 49^\circ 20'; \quad D_{\min} = 38^\circ 40'$$

A "thin" prism is one for which $A \gg 15^\circ$, so that θ (radians) $\approx \sin \theta$. This gives

$$D_{\min} \approx (n - 1)A$$

Reflection at Curved Surfaces. The element of area round a point on the surface is regarded as part of the tangent plane at that point. First consider a spherical surface, Figs. (7a) and (b), and let the aperture be small compared with the radius

FIG. 3. a, b and c show three methods of using the 45° prism. (d) is a constant deviation prism as used in spectrometers.

FIG. 4. Image formation by plane surfaces. (a) point object, (b) extended object (c) image by diffraction of a point object.

FIG. 5 (a). Formation of caustic by refraction. P, point-object P', position of point-image for small angles of incidence

FIG. 5 (b). Image by refraction of an extended object.

of curvature. In each Figure, O is the center of curvature, OP is a radius, and O' is the "pole" of the mirror. A ray parallel to the axis is reflected to a point F, the focus. In Fig. 7(a), F is in front of the mirror; in Fig. 7(b) it is behind, so that the reflected ray *appears* to come from F. For small apertures $O'F \approx PF$ and the position of F is independent of O within this limitation. This gives for O'F, the focal length $f = \frac{r}{2}$.

Image Formation. For an object of small dimensions, the image can be obtained by drawing two rays only: (a) a ray through O—this strikes the mirror normally and is returned along the same path; (b) a ray parallel to the axis—this is reflected through the focal point F. In Fig. 8, AB is the object and A'B' the image. In Fig. 8(a) the image is real, in Fig. 8(b) it is virtual. An image is real when the reflected rays actually pass through points in it; it is virtual if they have to be traced back, so that they only appear to come from the image.

Conjugate Foci. In Fig. 9(a) a point object A produces a point image A'. If A and A' are interchanged, the rays take identical paths but the arrows are reversed, A and A' are called conjugate foci. In Fig. 9(b) the image A' in the convex mirror is virtual. The relationship between the angles is as follows:—

$$\gamma = \theta + \beta, \quad \beta = \theta + \alpha; \quad \therefore \alpha - \gamma = 2\beta$$

For small apertures

$$\alpha = PO'/O'A, \quad \beta = PO'/O'O, \quad \gamma = PO'/O'A'$$

$$\therefore \frac{1}{v} + \frac{1}{u} = \frac{2}{r} = \frac{1}{f}$$

This is a purely quantitative relationship. For general application it is necessary to adopt a convention regarding signs. Distances are always measured from the mirror, and the direction of the incident light is reckoned positive. As an example let $u = 8$ and $r = 6$.

FIG. 6. Deviation by prism. (a) general case, (b) condition for minimum deviation.

FIG. 7. Reflection at spherical mirrors (a) Concave (b) Convex.

FIG. 8. Image formation in spherical mirrors. (a) Concave (b) Convex.

Concave Mirror	Convex Mirror
u and r negative $u = -8, r = -6, f = -3$ $\therefore \frac{1}{v} = -\frac{1}{3} - \left(-\frac{1}{8}\right) = -\frac{1}{4.8}$ $v = -4.8$	u negative and r positive $u = -8, r = +6, f = +3$ $\therefore \frac{1}{v} = -\frac{1}{3} - \left(-\frac{1}{8}\right) = -\frac{11}{24}$ $v = +2.18m$

FIG. 9. Conjugate foci.

The magnification

$$m = \frac{A'B'}{AB} = \frac{v}{u}$$

This is positive if v and u have the same sign as with the real inverted image of a real object, Fig. 8(a). It is negative if u and v are of opposite sign as with the virtual erect image of a real object, Fig. 8(b).

The axial magnification of an object of finite axial dimension is given by differentiating the above equation.

$$-\frac{dv}{v^2} - \frac{du}{u^2} = 0, \quad \therefore \frac{dv}{du} = -\frac{v^2}{u^2}$$

This shows that if an object is moved towards the mirror a distance du , the image will move $dv = -v^2 du/u^2$. Thus the image will move more rapidly when u is small.

Parabolic Mirror. For large apertures for which the angle β is not small, the rays of a parallel axial beam are not all brought to a focus at F but form the envelope of a cusp, as in Fig. 10(a). A parabolic mirror brings all the rays of such a beam to the same focus, [see Fig. 10(b)].

Refraction at Spherical Surfaces. The geometry of Fig. 11(a) gives for a surface of small aperture

FIG. 10. Reflection by mirrors of wide aperture (a) Spherical, (b) parabolic.

FIG. 11. Refraction at spherical surface of separation between two media.

If we put $v = \infty$ so that the rays are parallel after refraction and put f_1 for the corresponding value of u

$$\frac{n}{r} - \frac{1}{f_1} = \frac{1}{v}$$

If we put $u = \infty$, so that the incident rays are parallel, the corresponding value of v is given by

$$\frac{n}{r} - \frac{1}{f_2} = \frac{1}{v} \quad \therefore \frac{n}{f_2} - \frac{1}{f_1} = 0$$

For an object AB, Fig. 11(b), we obtain the position of the image by drawing two rays from B; the first parallel to the axis, thereby passing through F_2 after refraction; the second passing through F_1 thereby becoming parallel to the axis after refraction.

$$m = \frac{f_1}{u - f_1} \quad \text{or} \quad \frac{v}{f_2}$$

Lenses. Figure 12 shows three media separated by spherical surfaces. Considering each surface in turn

$$\frac{n_2}{n_1} \cdot \frac{1}{w} - \frac{1}{u} = \left(\frac{n_2}{n_1} - 1 \right) / r_1$$

$$\therefore \frac{n_2}{w} - \frac{n_1}{u} = \frac{n_2 - n_1}{r_1}$$

Similarly

$$\frac{n_3}{v} - \frac{n_2}{u} = \frac{n_3 - n_2}{r_2}$$

adding,

$$\frac{n_3}{v} - \frac{n_1}{u} = \frac{n_3 - n_2}{r_2} + \frac{n_2 - n_1}{r_1}$$

In the case of a lens, $n_3 = n_1$, giving

$$\frac{1}{v} - \frac{1}{u} = \left(\frac{n_2}{n_1} - 1 \right) \left(\frac{1}{r_1} - \frac{1}{r_2} \right)$$

with air on either side of the central section, $n_1 = n_3 = 1$, and we can put $n_2 = n$.

$$\therefore \frac{1}{v} - \frac{1}{u} = (n - 1) \left(\frac{1}{r_1} - \frac{1}{r_2} \right)$$

If we put $u = \infty$ then $v = f$, the focal length,

$$\therefore \frac{1}{f} = (n - 1) \left(\frac{1}{r_1} - \frac{1}{r_2} \right)^* \quad ; \quad f = \frac{r_1 r_2}{(n - 1)(r_2 - r_1)}$$

$$\text{Lateral magnification } m = \frac{v}{u} \quad \text{or} \quad \frac{f}{u - f}$$

$$\text{Axial magnification } \frac{dv}{du} = - \frac{v^2}{u^2}$$

$$\text{Example } r_1 = 10, \quad r_2 = 15, \quad \mu = 1.6$$

* Some authors give this equation with a + sign in the second bracket. In such a case it is necessary to use different signs for convex and concave surfaces, a confusion which is avoided by the simple convention adopted in this article.

FIG. 12. Lens.

With the convex lenses the focus is on the far side of the lens from the source; with the concave lenses it is on the same side as the source. With plano-convex and plano-concave lenses, $1/r$ for the plane surface is zero.

Defects in Mirrors and Lenses. An aperture which is large compared with the focal length introduces errors in both mirrors and lenses. One of these is the axial spread of the focus as shown in Fig. 10(a). The amount of spread for a mirror of aperture 2θ is

$$\frac{r}{2} \left(\frac{1}{\cos \theta} - 1 \right)$$

Astigmatism results when the object is situated off the axis. The reflected pencil is brought to a focus at a point I, also off the axis, and is spread into an axial line Q_1Q_2 , as in Fig. 13(a). If the mirror is turned through a small angle, the point I describes a line called the first focal line. Q_1Q_2 is the second focal line and is perpendicular to the other. In between there is a region where the reflected pencil is the nearest approach to a circle; this is called the circle of least confusion.

Figure 13(b) shows longitudinal spherical aberration in a lens; rays very close to the axis pass through the focal point as defined for a thin lens, while increasing divergence brings the focus nearer to the lens. Figure 13(c) shows chromatic aberration—the focal length, even for a thin lens, being a function of the wavelength. This is because n varies with the wavelength and increases as the wavelength decreases. Thus the focal length for violet is less than for red.

Curvature of the Field. The image of a plane object lies, in general, on a slightly curved field (Fig. 14), and this combines with the effects of astigmatism. Pincushion distortion results when a lens is used as a magnifying glass; barrel distortion results when an object is viewed through a lens at some distance from the eye.

Systems of Lenses. The inverse of the focal length of a lens is called the power of the lens. If

FIG. 13. Image defects. (a) Astigmatism, (b) Longitudinal spherical aberration, (c) Chromatic aberration.

FIG. 14. Image distortion. (a) Object, (b) pincushion distortion, (c) barrel distortion.

the unit of length is the centimeter, the unit of power is the diopter:

$$D = \frac{1}{f}$$

If a number of thin lenses are in contact, the power of the combination is the *algebraic sum* of the individual powers. As an example, consider two thin lenses for which $f_1 = 10$ and $f_2 = -15$ cm.

$$D_1 = \frac{1}{10} = 0.1 \text{ diopter}; D_2 = -\frac{1}{15} = -0.0667 \text{ diopter}$$

$$D = 0.1 - 0.0667 = +0.0333$$

$$\therefore f = +30 \text{ cm}$$

If two coaxial lenses are separated a distance d , then the focal length of the combination is given by

$$\frac{1}{f} = \frac{1}{f_1} + \frac{1}{f_2} - \frac{d}{f_1 f_2}$$

For a minimum longitudinal spherical aberration, the distance d should be

$$d = f_1 - f_2$$

OPTICS, PHYSICAL

In this branch of the subject of optics, we deal with phenomena connected with the nature of light itself. We assume that it is a transverse wave motion and that the underlying principles are embodied in the electromagnetic theory conceived by James Clerk Maxwell (1831–1879). A very brief outline of the major phenomena will be all that can be attempted in this article.

An excellent prerequisite to an understanding of the progress of light is Huygens' principle. Christian Huygens (1629–1695), a contemporary of Sir Isaac Newton, doubtless got the idea of

wave propagation by observing the progress of ripples on a Dutch canal. The famous principle, applicable to surface waves on a liquid, to sound waves and to light waves, is that *each point of a wave front may be regarded as a source of new waves*. In Fig. 1, the wavefront W may be regarded as the envelope of an infinite number of wavelets forming from the preceding wavefront W' , and W' may be likewise formed from W .

FIG. 1

Interference. A very important special case of the superposition of waves occurs when two identical wave trains W_1 and W_2 , of wavelength λ (Fig. 2), start out in phase from a source S and travel to a point of crossing S' —the one train going directly to S' , the other train going by way of a reflecting (or refracting) device M , and thus traversing a greater distance. The "distance" in each case is known as the *optical path*. What will be the effect at S' due to the superposition of the two coherent wave trains? The path difference taken by W_2 and W_1 is arranged experimentally so that it is a whole number of half wavelengths, or

$$(SM + MS') - SS' = n \frac{\lambda}{2}$$

- (i) when n is odd, there is *destructive interference*
- (ii) when n is even, there is *constructive interference*.

FIG. 2

In (i) the amplitudes of the two waves will cancel, since there is a phase difference of 180° , and light plus light will produce darkness at the point S' . In (ii) the amplitudes of the two waves will add, and there will be a maximum intensity at the point S' . It is assumed that the vibrations of the two wave trains are in the same *plane* in each instance. If they are not, a new effect is observed. For points near S' on either side, there will be gradations between zero and a maximum intensity. In the hands of outstanding experimenters such as Albert A. Michelson (1852-1931) the phenomena of interference have been put to great practical use in the measurement of extremely minute distances and angles (see INTERFERENCE AND INTERFEROMETRY).

It was the behavior of light during interference that enabled Thomas Young (1773-1829) to enunciate the wave theory of light and thus to upset the corpuscular theory which had been held by Newton. Material particles would not show interference, but wave trains—under the carefully specified conditions—would do so. As Young's crucial experiment is performed today, a train of plane waves W of wavelength λ is incident upon a screen C_1 (normal to the plane of the diagram, Fig. 3) which has cut in it a narrow slit S that serves as a line source of an emerging train of semicylindrical waves W' , in accord

FIG. 3

with Huygens' principle. Parallel to C_1 and relatively far away is a second screen C_2 which has cut in it two narrow slits S' and S'' , separated by a distance D and equally disposed on the two sides of the normal to C_1 at S . By Huygens' principle, S' and S'' , being parts of the same wave front, will send out wave trains that are coherent. If the normal through S cuts a third screen C_3 , that is parallel to the other two, at P_0 ; then at this point there will be zero path difference between it and the two slits S' and S'' . A bright line of light will be seen here, due to constructive interference. For two other points, P_1 and P_1' ,

equidistant from P_0 , the path difference $P_1S'' - P_1S'$ will be λ . Here again there will be constructive interference. Upon the screen C_3 there will be seen an interference pattern.

Diffraction. In general, the term diffraction denotes the departure of a train of waves from a straight course. Thus, ocean waves, parallel to the shore outside of an inlet, are seen, when they enter the harbor, to run along the inner shores—diffracted by the passage from the inlet to the harbor. Sound waves in a concert hall are readily heard in the "shadow" of a column that supports a gallery. By the same principle, light waves bend into the geometrical shadow when passing a straight edge. If, in the discussion of interference from two slits (Fig. 3), the widths of the slits were increased so as to include a larger number of "points" on the incident wavefronts, then the effects on the third screen C_3 would be more complex (see DIFFRACTION BY MATTER AND DIFFRACTION GRATINGS).

Dispersion. As used in optics, dispersion implies the separation of a light beam of more than one wavelength into its component parts. The operation can be effected by means of a diffraction grating or by a prism. In the simple case of dispersion by a grating G (Fig. 4), the

FIG. 4

wavelength λ , the angle of dispersion θ and the distance a between the centers of any two consecutive openings are related by $n\lambda = a \sin \theta$, where n , a positive integer, known as the *order* of the spectrum, is the number of whole wavelengths difference in path between the observer's eye and the centers of any two consecutive openings—assuming that parallel light is incident upon the grating. For dispersion by a prism, the angular spread of spectrum between the limits λ_1 (e.g., violet) and λ_2 (e.g., red) is given by $\alpha \approx A(n_1 - n_2)$ if the angle of the prism A is "small," say 15° or

less, and the prism is very nearly at minimum deviation for the extreme wavelengths. Prismatic dispersion is observed with a spectrometer or a spectroscope. The most celebrated example of prismatic dispersion was Newton's experiment with a prism held in the path of sunlight. The measure of dispersion depends upon a definite prism of given material and refracting angle, together with the values of the wavelengths involved. The *dispersive power* of the prism

material is defined by $p = \frac{n_1 - n_2}{n_1 - 1}$ between the limits 1 and 2, the center of the range being at some intermediate wavelength λ_3 . The angular dispersion of a given prism, or rate of change of deviation D with wavelength, may be regarded as the product of the quantity dD/dn , calculable by geometrical optics, and the quantity $dn/d\lambda$ (a property of the material). The last may be found from the *normal dispersion curve* (Fig. 5) plotted from data taken with a spectrometer using a prism of the given material and employing light

FIG. 5

sources emitting known wavelengths. The angular dispersion is found from a consideration of the equation

$$\frac{dD}{d\lambda} = \frac{dD}{dn} \cdot \frac{dn}{d\lambda}$$

In normal dispersion, the index of refraction decreases with wavelength; i.e., the velocity of light in the material increases with wavelength, and the rate of change of index with wavelength decreases with greater wavelengths. The phenomenon of dispersion is of prime importance in the science of spectroscopy but is a decided liability in the design of lenses for optical instruments, since any one lens by itself will not focus all colors at the same point. Exceptions to the general trend of index variation with wavelength are very common for certain substances throughout particular wavelength bands. The topic of anomalous dispersion is to be treated under the subdivision absorption spectroscopy (see ABSORPTION SPECTRA).

Polarization. Although the wave theory has been very satisfactory in "explaining" the phenomena of interference and diffraction, the crucial test for the necessity of that theory was not presented. What sort of waves are they? Are they longitudinal (as in sound), or circular (as in or on a water surface), or are they transverse (as

along a violin string)? Strong experimental evidence, as well as the electromagnetic theory of light itself, point to the transverse type of wave form for light—as well as for radiant heat, radio waves, and the other regions of the so-called *electromagnetic spectrum*. In Fig. 6(a) imagine that a beam of natural light is emerging from the paper at O and that the "light vectors" can take in turn any possible direction making an angle with the x-axis. If, now, a very finely ruled grill PP' ("polarizer") is placed in the beam as in Fig. 6(b), only those vibrations, or components of vibrations, which are parallel to PP' will be transmitted. The light that emerges will be *plane polarized*. Now let a similar grill AA' ("analyzer") Fig. 6(c) be placed in this transmitted beam, with an angle θ between the directions PP' and AA'.

FIG. 6

Then only those vibrations, or components of vibrations, emerging from PP' which are parallel to AA' will be transmitted by the latter. The incident light (from PP') has therefore been "analyzed." An everyday example of plane polarization was first observed by Etienne Louis Malus (1775-1812) through a chance "analysis" of sunlight reflected from a distant window. The Malus effect may be understood from Fig. 7. AO is a beam of natural light in the plane of the paper, incident upon the surface MM' at an angle i . The plane of the paper is the plane of incidence and MM' is perpendicular to it. The beam of natural light has as many light vector components at right angles to the plane of incidence (· · · · ·) as there are in that plane

FIG. 7

(// //). Malus found that the reflected beam (OB) is partially plane polarized, which means that there are in it more of the (· · · ·) components than there are of the (// //) components. The situation is reversed in the refracted beam (OC). Several years later, David Brewster showed that if the reflected and refracted beams are at right angles to each other, the polarization of the former is complete and that the tangent of the then angle of incidence is the index of refraction of the material (for that wavelength).

Optical Activity. It is not always true that a beam of plane polarized light maintains its vibrational direction as it proceeds into a transparent substance. Many materials actually rotate the plane of vibration by an amount that depends directly upon the distance traversed. *Optical activity* is exhibited by quartz, sodium chlorate, turpentine, sugar crystals (even if dissolved in water), etc. In the case of a solution, the rotation is also proportional to the concentration, and it may be clockwise or counter-clockwise. The wavelength of the light and the temperature are also factors in the total rotation observed. The apparatus used in the measurement of the angular displacement of the incident beam is a *polarimeter*.

Double Refraction. Certain materials, such as quartz, mica, Iceland spar and tourmaline, are able to refract a beam of light into two portions which, in general, travel thereafter in different directions. The phenomenon of *double refraction* was first described in 1669 by Erasmus Bartholinus. In Fig. 8 we imagine a beam of natural light of a

FIG. 8

given wavelength to fall upon the face AB of a crystal of Iceland spar (a clear form of calcium carbonate). One part, after passing the interface, travels on through the crystal in accord with Snell's law, and is known as the *ordinary* beam. The other part of the incident beam, after passing the interface, goes off at an angle with the first part. This is the *extraordinary* beam. If the crystal faces are parallel, the two beams will emerge parallel. It was soon found that they are plane-polarized at right angles to each other. The symbols (·) and (//) serve to denote this fact. Each crystal has an optic axis along which optical properties remain constant. If the incident light is normal to, or parallel to, the optic axis, there is no separation of the ordinary and extraordinary beams. Huygens explained double refraction of Iceland spar in terms of concentric spherical and ellipsoidal wavefronts (Fig. 9). The small double-headed arrows denote the vibrational directions of the transverse waves.

Photoelasticity. Many ordinary materials, such as plastics, can be made doubly refracting if they are placed under a stress. This new property will

FIG. 9

FIG. 10

show up if the specimen is placed between two "crossed" polarizing sheets (Fig. 10). Natural light is plane-polarized by the first sheet (polarizer) P and is then split by the specimen into ordinary and extraordinary beams, O and E. The second polarizing screen (analyzer) A suppresses one component of each beam so that the light vectors O' and E' that emerge from the analyzer are in the same plane and are in the condition to show interference at the screen.

OSCILLOSCOPES

The cathode-ray oscilloscope is an instrument that displays changing events in graphical form on the screen of a cathode-ray tube. The display is usually presented in terms of X-Y coordinates, with time represented horizontally from left to right, and the electrical analog of the event by a vertical displacement, up or down from some zero point (the abscissa and ordinate, respectively) (see ELECTRON OPTICS).

The first known use of the cathode-ray tube to display changing phenomena occurred in 1897, the same year that the tube was used to prove that cathode rays were electrified and would respond to a magnetic field. As the oscilloscope has come into greater use, it has been required to permit more and more accurate measurements of time and amplitude, directly from the display if possible. The engineering efforts to satisfy these requirements have influenced the basic philosophy of the instrument, have initiated developments in circuitry and components as well, and have resulted in sophisticated instruments that are actually small but complex "systems." For example, some "straightforward" oscilloscopes

meant for broad general-purpose laboratory use contain more than 150 vacuum tubes and semiconductor devices, while a sampling oscilloscope will contain nearly 250. Other instruments, designed to measure and automatically print out several parameters of semiconductor devices at the rate of several per second, contain over 600 semiconductors and tubes. Actually, in this last example, the cathode-ray tube has assumed the important but subsidiary function of a monitor for setting up and observing the desired performance of the testing equipment.

The events displayed by an oscilloscope are usually referred to as signals, and the parameters of the signal which it is desired to observe determine the characteristics the instrument must have. The design of an instrument, therefore, should reflect the desired range of signals it is expected to display. An instrument to deal with a narrow range of uniformly repetitive signals will be quite simple and will exhibit a different design philosophy than one expected to deal with arbitrary signals. These latter impose the most stringent design requirements, as there is no way of anticipating the time of signal occurrence, how soon it will occur again (if ever), duration, and its character or "form" (which determines its content).

An oscilloscope consists of three or four basic elements: cathode-ray tube, time-base generator, vertical deflection channel and power supply (which is quite important, as it sets the limits to both long-term and short-term stability of performance of the other elements). (Many would say that the signal pick-up is a basic element since it determines whether the instrument has a "good" signal to display.)

The case of a signal consisting of a single arbitrary event illustrates the relationship between these basic elements. Such a signal, or one whose duration is very short compared with the time until its next occurrence, presents a special problem whose solution permits viewing almost any other kind of signal. The problem can best be stated in the form of a question: How can all of such a signal be seen when the chain of complex events which permit it to be displayed must wait until its occurrence to be initiated?

The time relationships involved require that the signal not appear on the vertical deflection plates of the cathode-ray tube until the time base has been impressed on the horizontal deflection plates. Clearly, the signal must be "held up," stored, or somehow delayed until the sweep generator is well started and the electron beam in the cathode-ray tube is flowing. Normally this delay is performed in the vertical amplifier by a transmission line which requires a large amount of time for the signal to traverse compared to the onset of the signal and the starting time of the sweep.

Signal amplifiers in the cathode-ray oscilloscope are usually required to respond accurately to both the dc level at which a signal may occur and the signal itself, no matter how transient it

may be. At the present time, signals between 10^{-11} and 10^{-12} second are of interest, and present-day vacuum tube amplifier techniques are simply incapable of handling such a range of signals.

This problem has been approached in several ways, using vacuum tubes, semiconductors and a combination of the two technologies.

The vacuum-tube approaches reflect the fact that electrical currents and fields take time to move from place to place—whether through the space in a vacuum tube or along a conductor from one component to another. This fact makes it possible to space electrical elements physically so that they will influence the same electron or signal at different times. Consequently, we can apply the same deflecting field to the same electron or amplify the same signal a number of times at successive intervals. Sizeable improvements in bandwidth at a given deflection sensitivity in a cathode ray tube, or in gain at a given bandwidth in an amplifier, are possibly by these techniques. Devices designed in this way are often referred to as "distributed deflection plate" cathode-ray tubes or "distributed" amplifiers. (Traveling wave amplifiers, cyclotrons, klystrons and magnetrons all employ the principle of using the same field to affect the same electron at successive instants of time.)

Semiconductor devices in the proper physical form are capable of responding in exceedingly short periods of time—a few picoseconds (10^{-12} second), in fact. This capability, coupled with the recently developed microcircuitry or deposited film technology, should make some interesting and useful devices possible.

Another way in which an apparent increase in bandwidth can be obtained is by the sampling method. It is possible to generate very short voltage pulses in a very precise manner, both as to time of occurrence and form. If such a pulse is combined with a repetitively recurring signal at successively later instants (in relation to some arbitrary "point" on the signal), a series of voltage pulses is developed whose amplitude varies in the same manner as that of the signal in question, but whose duration is expanded by as much as is desired. In other words a signal of very short duration can be expanded into one of long duration, which can be handled by conventional amplifier techniques. An effective increase in bandwidth of 100 times or more can be obtained by this method (see PULSE GENERATION).

The development of deposited film technology makes it possible to obtain extremely wide-range performance never before attainable with vacuum tube or even conventional transistor technology. These new techniques hold a great deal of promise for obtaining increased performance in the oscilloscope art.

In at least one respect, the oscilloscope differs from most other instruments; it is expected to display the change in some phenomenon without distortion in either time or magnitude. In contrast with most other instruments, it does not deal with only one aspect of a phenomenon, such as an

average value, a peak value, the time between two events, the number of events, etc. In these cases, the attributes of no concern can be distorted if necessary to facilitate measuring the desired attribute. The oscilloscope, however, must display the "way" in which something changes, and it should "process the information" between the receiving of it and the displaying of it in an essentially passive manner.

Consequently, the use of the oscilloscope implies that it "displays" precisely what is put into it (otherwise it would not be very useful!). This is not absolutely possible in the general case because certain signals whose characteristics fall near or outside the range of the oscilloscope amplifier are distorted to some degree. Such distortion is inevitable. The problem is to determine which kind of distortion is acceptable.

Ordinarily, bandwidth has been considered to be the principal criterion of performance of an amplifier. However, when an amplifier is handling arbitrary signals, it is nearly impossible to adjust it to give undistorted response over the whole range of performance by using conventional bandwidth-testing techniques. The most effective method that has been developed to adjust an amplifier for uniform undistorted response is by the use of step functions or square waves. A step function is a "no-time" transition from one dc voltage level to another. A square wave is simply a series of step functions "alternating" between two dc levels of voltage in a regular manner. The value of a square wave is that its quality can be evaluated by eye with a precision unmatched by most conventional, easily used bandwidth-testing techniques. Once the criteria of distortion have been agreed upon, evaluations can be made which are limited only by the skill and experience of the viewer.

Several kinds of distortion of a step function may occur in an amplifier. For example, it can be adjusted to give the shortest possible risetime, since the step function rises in "no time." Although such an adjustment gives the best possible reproduction of the actual transition, it also causes the signal to "overshoot," adding high frequencies to the display that were not present in the original signal. Conversely, the amplifier can be adjusted so that the dc levels between the transition are completely undisturbed and the result is a gradual transition from one voltage level to the other which subtracts high frequencies from the signal. However, there is an optimum region of performance where the transition takes place as rapidly as is possible under the circuit conditions but with no overshoot and a minimum of detectable distortion in the stable voltage levels following the transition. In this situation, the circuit itself determines the response to a step function, the deteriorated portion of the step function can be computed from the observed risetime and the known amplifier risetime, and most important, there is never any question whether a particular element of the display is due to the amplifier or is actually present in the signal. If something appears in the display, it is

present to at least that degree in the signal. It may be present in the signal to a greater degree than the display indicates, in which case responses of about one-fifth of the risetime of the amplifier can be estimated to a reasonable accuracy.

The problem of determining fidelity of response is a never-ending one. The testing square wave must be "square" enough that it does not contribute any distortion to the ultimate display. However, only by having a measuring system with capabilities much beyond the characteristics of the testing square wave can we be reasonably confident of the quality of this signal. But we can only test this latter measuring system for fidelity of response by having another testing square wave of known fidelity so that any distortion in the amplifier will be apparent to the user. The solution to this problem takes on the character of attempting to lift oneself by one's own bootstraps and, of course, is never satisfactorily resolved.

OSMOSIS

If, into the bottom of a jar containing water, a solution of cane sugar is introduced with care so as to avoid mixing, not only will the molecules of cane sugar diffuse into the water but the molecules of water will diffuse into the sugar solution. These processes will go on until the concentration of sugar, and of water, is the same throughout.

If the solution is placed in a container, whose walls are relatively impermeable to the sugar while being permeable to the water, and the container is placed in water, the water will pass from the outside into the container. The term osmosis is usually restricted to the passage of water. If the influx of the water results in an overflow of solution to somewhere other than the surrounding water this overflow will continue until all the sugar is removed from the container. If the container is closed, water will continue to enter until there is sufficient stress in the stretched walls to cause a pressure on the solution inside; this will eventually stop the influx. Of course, if the walls of the container are not completely impermeable to sugar, then the sugar will be escaping into the water outside the container and this will go on until the concentration of sugar is the same out-

side and inside. If the walls of the container were impermeable to water but permeable to solute, the latter would escape. The cause of this osmosis, this "pushing," of water into the solution is that the tendency of the water molecules to escape from the pure water is greater than that of the water molecules in the solution. Consider water in contact with a limited volume of air. Of those molecules of water striking the surface some will have sufficient energy to escape into the air and this escape will result in net loss to the air which will continue until the concentration of water vapor molecules there is such that the rate of escape from the air (into the water) equals the rate of escape from the water (into the air). If the volume of the air space is fixed, the pressure will rise. Just as the temperature of all bodies is the same when they are in thermal equilibrium, although their heat content per unit volume varies with their specific heat, so the escaping tendency of the water is the same in all systems when they are in aqueous equilibrium, whether the system is pure water, solution, gas phase, wettable solid, etc. The same concept can be applied to any substance, say mercury in pure mercury, in air containing mercury vapor, and in an amalgam with another metal such as zinc. The term osmosis is usually restricted to the passage of water from a solution where the escaping tendency is higher to a solution where it is lower. Moreover it is usually restricted to the passage through a solid or liquid barrier which prevents the solutions from rapidly mixing. It is not used for the passage of water in the form of vapor through the air from a dilute solution to a stronger solution in the same confined space, although the process is fundamentally the same. It is sometimes restricted to the case where the barrier is semipermeable, that is, lets through water but not solute.

The escaping tendency of water is lowered by the addition of a solute. If the molecules of the solute have no other effect than to reduce the number of molecules of water in unit volume, then the escaping tendency of the water will be reduced proportionately to the reduction in the mole fraction of water, N_1 , the ratio of the moles of water to the sum of the moles of water and solute. Such is a "perfect" solution. If, however, there is some attraction between the solute and water molecules, a smaller fraction of the latter will have energy sufficient to escape—a "non-perfect" solution. The escaping tendency is increased by pressure. Hence a solution in which the water has lower escaping tendency than it has in pure water at the same pressure, P^0 , can be brought to water equilibrium by a sufficient increase in the pressure on the solution to a value P . This sufficient increase, $P - P^0$, is the osmotic pressure of the solution. In general we cannot state $P - P^0$, the osmotic pressure, knowing only N_2 , the ratio of moles of solute to the sum of the moles of water plus solute, the mole fraction of solute, ($N_2 = 1 - N_1$).

What we can say is, that if in a solution with a mole fraction N_2 of solute under a pressure P the water has the same escaping tendency as it has in

pure water at the same temperature and at a pressure P^0 , then $dP/dN_2 = A/B$ where dP/dN_2 is the increase of P relative to increase of N_2 to keep the escaping tendency unchanged; A is the decrease of escaping tendency relative to increase of N_2 when P is unchanged; and B is the increase in escaping tendency relative to increase in P when N_2 is unchanged. For dilute solutions A/B approximates to RT/V_1 and so $P - P^0$ approximates to N_2RT/V_1 where V_1 is the volume of one mole of water, R is the constant $82.07 \text{ cm}^3 \text{ atm/deg}$, and T is the absolute temperature. For very dilute solutions N_2/V_1 approaches n_2/V , the number of moles of solute in a volume V of solution and $P - P^0 = n_2RT/V$ (van't Hoff's equation). This gives an osmotic pressure of 1 atm for one mole of solute in 22.4 liters at 0°C . There is a departure from both these equations for stronger solutions. The fact that one mole of a perfect gas in 22.4 liters at 0°C exerts a pressure of 1 atm, coupled with the above, has led some to say that the osmotic pressure is the bombardment pressure of the solute molecules. It is correct to say that for very dilute solutions the osmotic pressure of a solution is equal in magnitude to the pressure the solute molecules would exert if they were alone in the same volume and behaved as a perfect gas, but that is another matter.

To measure the osmotic pressure a semipermeable membrane must be prepared which itself can stand sufficient pressure, or it must be deposited in the walls of a porous pot so that the pressure can be sustained. With the solution being inside and water out, pressure is applied to the former until there is no net movement of water.

Observations by Berkeley and Hartley showed that for 3.393 gms of cane sugar per 100 gms H_2O , the osmotic pressure at 0°C is 2.23 atm while the van't Hoff equation gives 2.17 atm since $n_2/V = 9.72 \cdot 10^{-5}$. If N_2/V_1 is used instead of n_2/V , the value of 2.22 is obtained. With stronger solutions the measured osmotic pressure exceeds that calculated: with 33.945 gms of sugar, 24.55 atm is the value measured, while van't Hoff's equation gives 18.41 and the other 21.8 atm. The observed value is given if, in calculating N_2/V_1 , it is assumed that each sugar molecule immobilizes five molecules of water.

The solutes in the vacuole of a plant cell are exposed to the inward pressure of the distended cell wall and that of the turgid surrounding cells. Water will pass into the cell vacuole from water outside as long as the total inward pressure on the vacuole falls short of the osmotic pressure of the solution in the vacuole. Passage of water into the vacuole dilutes the contents and lowers the osmotic pressure and increases the inward pressure by distension. The amount by which the inward pressure falls short of the osmotic pressure is called by some the suction pressure.

A substance such as cellulose or gelatin tends to take up water, the tendency decreasing with increase in water content until the stress in the substance causes a sufficient rise in the escaping tendency of the water in the substance. This process, which like osmosis is a movement from

higher to lower escaping tendency, is called imbibition, and the pressure on the substance sufficient to stop the uptake is the imbibitional pressure. Hence, if a plant cell with a cellulose wall, after coming to equilibrium with a solution, is transferred to water, the wall takes up water by imbibition and the vacuole by osmosis. The latter considers only the over-all movement from outside to vacuole and does not consider the movement from cellulose to vacuole, a process which is the reverse of imbibition. A plant cell in equilibrium with a solution having an osmotic pressure of 25 atmos would also be in equilibrium with air about 98 per cent saturated with water vapor. If the cell was transferred to a saturated atmosphere, it would take up water. We lack precise terms for the passage of water from air into the cellulose and into the vacuole. Condensation, which might be used, ranges more widely.

The escaping tendency of water is affected by factors other than concentration of solute and pressure. Increase of temperature increases escaping tendency. This is a complex problem involving not only transfer of water but also of heat. To a minor extent, the passage of water from pure water to a solution involves a heat transfer.

For many naturally occurring membranes which are not completely semipermeable, i.e., they let solute molecules through slowly, electro-osmosis is important. If the membrane tends to lose negative charges to, or take negative charges from, water or solutions, then the water molecules, in the pores of the membrane, will tend to take on an opposite charge to the membrane. If there is a gradient of electric potential across the membrane, the charged water will move in the appropriate direction. If the potential difference

is established by the use of electrodes, this is electro-osmosis.

With some membranes, particularly those containing protein, water may pass from a dilute solution on one side to water on the other—negative osmosis. Under such conditions if the solution was acid the membrane would be positively charged through the uptake of H^+ ions, leaving the water in the pores negative. The greater mobility of the H^+ ions relative to the anions will cause the side of the membrane towards the solution to be negative and so drive the negatively charged water in the pores across the membrane in the opposite direction to normal osmosis.

The rate of osmosis depends, not only on the excess of the escaping tendency of the water in the phase from which it moves over that in the phase to which it moves, but also upon the area of surface of interchange and the over-all resistance experienced by the water. The rate of shrinkage of the vacuole of a plant cell when it is placed in a strong solution at first seems surprisingly high. When allowance is made for the fact that the ratio of surface to volume increases as the linear dimension is reduced then it is realized that when the vacuole of a spherical cell of radius $30\ \mu$ shrinks to half its volume in say 5 minutes the passage of water is only 1 ml per $10,000\ \text{cm}^2$ per minute although the thickness of the layer between vacuole and external solution is of the order of $1\ \mu$ in thickness. Under other circumstances, this layer might be said to be relatively impermeable to water. It seems probable that much of the resistance resides not in the cellulose wall or cytoplasm but in the tonoplast which separates the latter from the vacuole.

P

PARAMAGNETISM

A substance is said to be paramagnetic if it is attracted to a magnetic field in contradistinction to a diamagnetic substance which is repelled by a magnetic field. Excluding FERROMAGNETISM, which is an extremely strong type of paramagnetism, paramagnetic substances can be roughly divided into 3 categories—strong, weak, and very weak paramagnets.

Strong paramagnetism is exhibited by elements of the iron, platinum, palladium, rare earth, and uranium groups and (generally) compounds formed from elements of these groups. For such elements the paramagnetism arises from unpaired electron spins associated with the non-valence electrons of the atoms, each unpaired electron behaving much as a particle having an intrinsic spin angular momentum and associated magnetic moment which is orbiting about the central nucleus. For compounds in which the paramagnetic ions are dispersed sufficiently so that there are only negligible interactions between the paramagnetic electrons, the magnetic susceptibility, which is the ratio of the induced magnetization of the sample, M , to the externally applied magnetic field strength, H , is given by $\chi = C(T - \theta)$ for small values of H/T , T being the absolute temperature of the sample. In this equation, called the Curie-Weiss Law after P. Curie (1905) and P. Weiss (1907), who did much of the early work on paramagnetism, C is called the Curie constant and was shown by Langevin (1905), using classical arguments, to be equal to $N\mu^2/3k$, N being the number of paramagnetic ions per unit volume, μ the magnetic moment of each ion, and k Boltzmann's constant. θ is called the Curie or Curie-Weiss temperature and may be either positive, negative, or zero depending on the particular compound being studied. If $\theta = 0$ the Curie-Weiss Law reduces to the Curie Law $\chi = C/T$. For $T \lesssim \theta$, interactions among the ions can no longer be ignored and the Curie-Weiss Law is no longer valid. Later quantum mechanical calculations have shown that in the limit where $\mu H/kT \ll 1$, the Curie-Weiss Law is still valid providing that in the Curie constant C , μ is replaced by

$$\mu_{\text{eff}} = g\mu_B \sqrt{J(J+1)}$$

where g is the Lande g factor, having a value of about 2, μ_B is the Bohr magneton $|e|\hbar/2mc$, and J

is the total angular momentum quantum number of the ion in question. For some ions, notably those of the iron group, the contribution of the orbital angular momentum is partially or totally quenched by the crystalline electric field, in which case μ_{eff} is better given by the equation $\mu_{\text{eff}} = g\mu_B \sqrt{S(S+1)}$ where S is the spin angular momentum quantum number of the paramagnetic ion. A more complete derivation of χ for arbitrary values of H/T and for negligible interactions gives for the classical derivation (Langevin, 1905)

$$\chi = \frac{N\mu}{H} L\left(\frac{\mu H}{kT}\right), \quad L\left(\frac{\mu H}{kT}\right)$$

being the Langevin Function of the argument $\mu H/kT$. A quantum mechanical derivation gives

$$\chi = \frac{Ng\mu_B J}{H} B_J\left(\frac{g\mu_B JH}{kT}\right), \quad B_J$$

being the Brillouin Function. The Langevin and Brillouin Functions are given by the formulas

$$L(x) = \coth x - \frac{1}{x} \text{ and } B_J(x)$$

$$\frac{2J+1}{2J} \coth \left[\frac{(2J+1)}{2J} x \right] - \frac{1}{2J} \coth \left[\frac{x}{2J} \right]$$

A plot of $L(\mu H/kT)$ vs $\mu H/kT$ is shown in Fig. 1.

FIG. 1

It is noticed that for small values of $\mu H/kT$ the Langevin Function reduces to $1/3(\mu H/kT)$ which gives the Curie Law, while for large values of $\mu H/kT$ the Langevin Function approaches an asymptotic limit, which results in the saturation of the magnetization of the sample. A plot of the Brillouin Function for a given ion has the same qualitative shape as that shown for the Langevin Function. At room temperature the strong paramagnetism of the electrons ranges from 10^{-3} to 10^2 cgs units.

Weak paramagnetism is a strictly quantum mechanical phenomenon exhibited primarily by metals and is associated with the conduction electrons near the top of the Fermi distribution. Only those electrons having an energy within approximately $2\mu H$ of the Fermi energy are able to reorient or align themselves in a magnetic field and change their energy state, since all energy states below the Fermi energy are filled. Thus only the fraction of the total number of electrons kT/kT_F , where kT_F is the Fermi energy and T is the absolute temperature of the sample, can contribute to the susceptibility. Ignoring interactions among the electrons the susceptibility is then given by

$$\chi = \frac{C}{T} \cdot \frac{kT}{kT_F} = \frac{C}{T_F}$$

which is independent of temperature. A more rigorous quantum mechanical derivation of the susceptibility for this case gives the result that

$$\chi = \frac{3 N \mu_B^2}{2 k T_F} - \frac{1}{3} \left(\frac{3 N \mu_B^2}{2 k T_F} \right) = \frac{N \mu_B^2}{k T_F}$$

where the first term is the paramagnetic contribution associated with the electrons assumed to be stationary (Pauli, 1927), while the second term is the diamagnetic contribution due to the spatial motion of the electrons (Landau, 1930). At room temperature the susceptibility of the conduction electrons in a metal ranges from about 10^{-4} to 10 cgs units.

The very weak paramagnetism associated with some nuclei is due to their intrinsic spin angular momentum and associated magnetic moment. The nuclear susceptibility is described by the Brillouin equation as given above with J replaced by the nuclear spin quantum number I . At room temperature the nuclear susceptibility is approximately 10^{-11} to 10^{-10} cgs units and so is generally swamped by the paramagnetism of the electrons if such is present.

Electron paramagnetism is often studied experimentally using the Faraday or Gouy methods or the indirect method of electron paramagnetic resonance. The only direct measurement of nuclear paramagnetism was performed by Lasarew and Shubnikov (1937) for protons in solid hydrogen, although the sensitive techniques of nuclear magnetic resonance have now been used to study most known paramagnetic nuclei.

PERIODIC LAW AND PERIODIC TABLE

When the chemical elements are compared in order of increasing atomic number, many of their physical and chemical properties are observed to vary periodically rather than randomly or steadily. This relationship, recognized empirically a century ago by de Chancourtois in France, Newlands in England, Lothar Meyer in Germany, and Mendeleev in Russia, is now known to be the logical and inevitable consequence of the fundamental periodicity of atomic structure. The familiar statement of the periodic law is this: "The properties of the chemical elements vary periodically with their atomic number." A more informative statement of this same law is: *The atomic structures of the chemical elements vary periodically with their atomic number; all physical and chemical properties that depend on atomic structure therefore tend also to vary periodically with atomic number.*

The periodicity of atomic structure (see ATOMIC PHYSICS) is described by quantum theory as developed through modern wave mechanics. Each successive electron, beginning with the first, that comes within the field of an atomic nucleus, occupies the most stable position available to it. The number of possible positions is limited by quantum restrictions which describe each position in terms of four quantum numbers, and by the Pauli exclusion principle that no two electrons within the same atom may have the same four quantum numbers. These electron positions, or energy levels, are grouped with respect to their average distance from the nucleus as "principal quantum levels or shells," designated by the "principal quantum number" $n = 1, 2, 3, 4, \dots$, successive integral values increasing in order of increasing average distance from the nucleus. The total capacity of each shell can be expressed as $2n^2$, being 2 for $n = 1$, 8 for $n = 2$, 18 for $n = 3$, and 32 for $n = 4$; no higher level actually contains more than 32 electrons.

These total capacities can easily be accounted for by the several quantum number restrictions and the Pauli principle. Within each principal

energy level are differently shaped regions called "orbitals," that can be occupied by electrons. The shape of each orbital is designated by the "orbital quantum number" l , which may only have integral values from 0 up to $n - 1$. The number of orbitals of each shape that can exist within a principal quantum level depends on the fact that an electron in an orbital is a charge in motion and therefore has magnetic properties which influence the orientation of the orbital in an external magnetic field. The possible orientations are designated by the "orbital magnetic quantum number" m_l , which may have values from 0 to plus or minus the orbital quantum number l . Thus when $n = 1$, l can only have the value 0, which means that only one orbital is possible, having orbital magnetic quantum number 0. When $n = 2$, l can have the values 0 and 1. For the value 0, one orbital is possible, but when $l = 1$, m_l can have values 0, $+1$, and -1 , corresponding to three orbitals. Four orbitals are therefore possible in the principal quantum level $n = 2$. When $n = 3$, the same kinds of four orbitals are possible, and in addition, l can equal 2. This gives five possible values for m_l : 0, $+1$, $+2$, -1 , and -2 , corresponding to five more orbitals for a total of 9. When $n = 4$, the same kinds of 9 orbitals are possible, and in addition l can equal 3. This gives seven possible values for m_l : 0, $+1$, $+2$, $+3$, -1 , -2 , and -3 , corresponding to 7 more orbitals for a total of 16. No principal quantum level uses more than 16 orbitals even though more are theoretically possible when $n = 5$ or more.

One additional property of an electron in an atom needs to be considered. This is its property as a magnet, irrespective of its orbital motion. This is designated by the "spin magnetic quantum number," which can have only the values $+\frac{1}{2}$ and $-\frac{1}{2}$. Since each orbital is uniquely specified by the first three quantum numbers, n , l , and m_l , the capacity of each orbital is thus limited to 2 electrons, and these only if, according to the Pauli principle, they are of opposed spins (differ in the fourth quantum number). The total capacity of each principal quantum level is therefore twice the number of orbitals within it, because this represents the total number of permissible combinations of four quantum numbers within that level. For example, the capacity of the $n = 4$ level is limited to 32 electrons by the fact that only 16 different combinations of the four quantum numbers are possible within that level; these electrons will occupy 16 orbitals.

The differently shaped orbitals having orbital quantum numbers $l = 0, 1, 2$, and 3 are commonly called s , p , d , and f orbitals. From the above discussion, it should be clear that within any principal quantum shell, there can be only one s orbital, three p orbitals, five d orbitals, and seven f orbitals. The p orbitals do not appear until $n = 2$, the d until $n = 3$, and the f until $n = 4$. Within any given principal quantum shell, the order of decreasing stability, and therefore the order of filling with electrons, is always s - p - d - f .

The periodicity of atomic structure arises from the recurrent filling of new outermost principal

quantum levels, but it is complicated by the fact that although the principal quantum levels represent very roughly the general order of magnitude of energy, there is considerable overlapping. This overlapping is such that the outermost shell of an isolated atom can never contain more than 8 electrons. In the building up of successively higher atomic numbers, electrons always find more stable positions, once a set of p orbitals in a given principal quantum level is filled, in the s orbital of the next higher principal quantum level rather than the d orbitals of the same principal quantum level. When this s orbital is filled, electrons then go into the underlying d orbitals until these are filled, before continuing to fill the outermost shell by entering its p orbitals. The building-up of the atoms of successive atomic numbers may be represented by the following sequence: $1s, 2s, 2p, 3s, 3p, 4s, 3d, 4p, 5s, 4d, 5p, 6s, 5d, 4f, 6p, 7s, 6d, 5f$. The periodicity of atomic structure thus consists of the recurrent filling of the outermost shell with from one to 8 electrons that corresponds to the steady increase in nuclear charge.

A period is considered to begin with the first electron in a new principal quantum shell and to end with the completion of the octet in this outermost shell, except, of course, for the very first period, in which the outermost shell is filled to capacity with only two electrons. From the order of orbital filling given above, it should be apparent that periods so defined cannot be alike in length. The first period, consisting of hydrogen and helium, has only two elements. The second period, beginning with lithium (3) and ending with neon (10), contains 8 elements, as does the third period, which begins with sodium (11) and ends with argon (18). The fourth period begins with potassium (19), but following calcium (20), the filling of the outermost (fourth) shell octet is interrupted by the filling of the d orbitals in the third shell. Thus 10 more elements enter this period before filling of the outermost shell is resumed, making the total number of elements in this period 18. In the fifth period, the first two outermost electrons are added in rubidium (37) and strontium (38), but then this outer shell filling is interrupted by the filling of penultimate shell d orbitals, which again adds 10 elements before filling of the outermost shell is resumed; this period also contains 18 elements. The sixth period begins as before with two electrons in the outermost shell, but then there is an interruption at lanthanum (57) to begin filling the $5d$ orbitals. Here, however, occurs an additional interruption, in which 14 elements are formed through filling of the $4f$ orbitals, before the remaining $5d$ orbitals can be filled, and in turn before the outermost shell receives any more electrons. Consequently here it takes 32 elements to bring the outermost shell to 8 electrons and thus end the period. The seventh period is similar but incomplete. In principle it would end with element 118, but artificial element 103 is the highest in atomic number known at the time of writing.

These elements which represent interruptions in the filling of the outermost s and p orbital octet

are called "transition elements" (where d orbitals are being filled), and "inner transition elements" (where f orbitals are being filled). This is to distinguish them from the other, "major group," elements in which underlying d or f orbitals are either completely empty or completely filled.

Physical properties of the elements that depend only on the electronic structure of the individual atom, such as the ionization potential and atomic radius, vary periodically with atomic number simply because of the recurrent filling of the outermost shell. Increasing the atomic number, by increasing the nuclear charge while adding to the outermost shell electrons increases the attractive

interaction between nucleus and outermost electrons more than it increases the repulsive forces among the electrons, with the result that the electronic cloud tends to be held closer (smaller radius) and more tightly (higher ionization energy), the more outermost shell electrons there are. For example, carbon (6) with half-filled octet has radius and ionization energy intermediate between the larger lithium (3) atoms with low ionization energy and the smaller fluorine (9) atoms with high ionization energy. Similar but smaller effects are observable for the addition of d or f electrons to underlying shells.

The bonding properties of elements also depend

on the electronic structure of the individual atom and therefore likewise vary periodically. For example, each period (except the first) begins with an alkali metal, lithium (3), sodium (11), potassium (19), rubidium (37), cesium (55), and francium (87), all of which show similar metallic bonding, crystallizing in a body-centered cubic lattice. Each has but one outermost electron per atom and can therefore form but one covalent bond. Each is very low in electronegativity and thus tends to become highly positive when bonded to another element. Crossing each period the elements become less metallic, higher in electronegativity, and able to form a greater number of bonds until limited by the number of outer shell vacancies rather than the number of electrons. The halogens, fluorine (9), chlorine (17), bromine (35), iodine (53), and astatine (85), each of which is next to the end of its period, are all nonmetals, highest of their respective periods in electronegativity and thus tending to become highly negative when bonded to other elements. Having seven, outermost electrons, each has but one vacancy permitting but one covalent bond.

Physical properties of the elements that are of greatest interest are usually properties that depend indirectly on the atomic structure but directly on the nature of the aggregate of atoms which results from the atomic structure. Such properties are melting point, density, and volatility. They may tend to vary periodically, but the periodicity is not necessarily consistent or even evident, because of abrupt differences in the type of polyatomic aggregate. For example, the identical

atoms of carbon may form graphite or diamond, depending on the kind of bonding, with entirely different properties resulting. Nitrogen follows carbon in atomic number, but because it forms N_2 molecules instead of giant three-dimensional structures like diamond or graphite, it is a gas with physical properties strikingly different from those of either form of carbon.

Among the most useful applications of the periodic law is to an understanding of the differences among compounds, whose properties also vary in a periodic manner. For example; oxides of elements at the beginnings of periods tend to be very stable, high-melting, nonvolatile solids of strongly basic character and practically no oxidizing power. Oxide properties change progressively across each period until toward the end, the oxides tend to be unstable, low-melting, volatile compounds, acidic in nature and of high oxidizing power. Such periodicity is recognizable throughout a very large part of chemistry.

In order to erect a framework upon which the myriad facts that accord with the Periodic Law can be organized, the chemical elements can be arranged in an orderly manner called a "periodic table." Any such arrangement¹ can be satisfactory if it organizes the elements in some order of increasing atomic number, showing the separate periods and at the same time grouping elements of greatest similarity together.

In Fig. 1 is shown a modern version of the periodic table², together with the "long form." Figure 2 shows the "long form" as currently most widely used. From left to right across the table are

Fig. 2. Periodic chart of the elements (reproduced with permission of copyright owner, Fisher Scientific Company).

the "periods," representing the elements in order of successively increasing atomic number and therefore progressive change in atomic structure. Across the period, the properties of the elements and their compounds tend to change from one extreme to the opposite. From top to bottom the periods are placed so that the most similar elements are grouped together. A distinction (shown by a physical separation) is made between "major groups" and "transition groups" because of the bonding dissimilarities originating in the availability, in the transition elements, of underlying *d* orbitals that are not available in the major group elements. In older tables, major groups are usually, although inconsistently, designated as "A" and transition groups as "B." In Fig. 1, the designations are consistently "M" (major) and "T" (transition). But whether in the major group or the transition group, the elements are arranged vertically on the basis of similarity in electronic configuration, which is then reflected in similarities in the physical and chemical properties of the elements and their compounds.

No amount of organization or correlation will ever alter the fact that each chemical element is an individual and unique, nor will the properties of any element be changed one iota by placing that element in any special position in a periodic table. Nevertheless, there is enough consistency to the structure and behavior of atoms to make any reasonable form of the periodic table an extremely useful framework upon which to organize and correlate an enormous quantity of chemical information³. The periodic law is truly one of the great generalizations of science.

PHASE RULE

The phase rule is a general equation $F = n - r - 2$, stating the conditions of thermodynamic equilibrium in a system of chemical reactants. The number of degrees of freedom or variance (F) allowed in a given heterogeneous system may be examined by analysis or observation and plotted on a graph by proper choice of the components (n), the phases (r), and the independently variable factors of temperature and pressure.

Josiah Willard Gibbs propounded the rule about 1877, and H. W. B. Roozeboom about 1890 began pioneering in specific cases. This rule

has been important in the development of metallurgy, the exploitation of salt deposits (e.g. Stassfurt, Germany and Searles Lake, Calif.), and the study of ceramic and mineralogic processes.

A phase is a homogeneous, physically distinct and mechanically separable portion of a system. H₂O has the three phases: water, vapor and ice. Each crystal form present is a phase. The relative amounts of each phase do not affect the EQUILIBRIUM.

The one-component system, water-vapor-solid, is unary. The components of a system are the smallest number of independently variable constituents by means of which the composition of each phase taking part in the equilibrium can be expressed in the form of a chemical equation.

With the components fixed in a system, variance—the degrees of freedom (F)—depends on the number of phases present. If water vapor alone is present, the system is bivariant since both temperature and pressure can vary within limits without affecting the number of phases; but if a second phase, liquid water, is present, the system is univariant and if either the temperature or pressure of the system in equilibrium is set, the other is automatically fixed as long as a second phase is present. A third phase, ice, makes the system invariant (the triple point), and any change in temperature or pressure, if maintained, results in the disappearance of one phase. Addition of another component forms a binary system, one degree of freedom is added, and the system, is univariant until a fourth phase appears and the system becomes invariant (the quadruple point).

Schematic phase equilibrium diagrams outline experimental observations of physical and chemical changes in the system as the conditions of temperature, pressure and composition are varied. For unary systems, the diagram has two dimensions, for binary systems, three, and for ternary systems, four, etc. Binary systems are easily plotted with pressure or temperature constant, while ternary systems may be treated similarly as condensed systems with both constant if the vapor pressure is less than atmospheric. This added restriction reduces the variance by one, and at constant temperature, composition relationships may be plotted on a triangular diagram. Quarternary or quinary systems and ternary systems above atmospheric pressure may be treated by projections of surfaces of thermodynamic stability, but more complex systems require a mathematical approach.

The simple one-component system, water, plotted with rectangular coordinates, i.e., pressure and temperature, shows a variety of concepts which may be extended to more complex systems (see Fig. 1 in STATES OF MATTER). Each area in the diagram is a bivariant, one-phase state. Each curve separating the areas is a univariant, two-phase state showing the conditions under which a transition of phase occurs. The fusion curve for the equilibria between the solid phase and the liquid phase, the sublimation curve for solid

and vapor, and the vaporization curve for liquid and vapor meet at the triple point. The three distinct phases differ in all properties except chemical potential. The end of the vaporization curve is a singular point, the critical point where liquid and vapor become identical, a restriction which reduces the variance by one so that F becomes zero.

In a binary (or higher) system, a liquidus is a curve representing the composition of the equilibrium liquid phase and a solidus represents the composition of the solid phase. The conjugate vapor phase is represented by a vaporous with tie-lines or conodes to the liquidus or solidus points in equilibrium. A minimum point for the existence of a liquid is the eutectic, sometimes (in an aqueous system) called the cryohydric point. In a ternary system the eutectics of three binary systems initiate curves leading to a ternary eutectic. If two liquids form a miscibility gap in the system, multiple quadruple points are possible. At a peritectic, a phase transition occurs at other than a minimum, i.e., one solid melts to another solid and a liquid. The solid may be a compound or a solid solution (mixed crystals) in which the composition of the solid varies with relative proportion of components and is shown by the solidus. A congruent melting point is a maximum in its curve, i.e., the solid melts to a liquid of the same composition. Where two phases become identical in composition, an indifferent or critical point exists. Where two conjugate phases become identical, the point may also be called a consolute point.

PHONONS

Many of the thermal and vibrational properties of solids can be explained by considering the material to be a volume made up of a gas of particles called phonons. This particle description is a method of taking into account the actual motion of the atoms and molecules in the solid. Since each atom possesses energy due to its thermal environment, and since there are forces between the atoms which keep the solid together, each atom tends to oscillate about its equilibrium

position. The formal mathematical development, obtained through solving the equations of motion of the array of individual atoms and molecules, indicates that the thermal energy of the solid is contained in certain combinations of particle vibrations which are equivalent to standing elastic waves in the sample and are called normal modes. Each normal mode contains a number of discrete quanta of energy $E = \hbar\omega$, where ω is the frequency of the mode (or wave) and \hbar is Planck's constant divided by 2π . Each of these quanta is called a phonon (in analogy with the light quanta or photon whose energy-frequency relationship is identical). The remaining discussion can be best understood by considering the phonons only as particles, each having an energy $E = \hbar\omega$, a momentum q , and a velocity $v = \partial\omega/\partial q \sim \omega/q$ (see QUANTUM THEORY).

Analogous to the energy levels of electrons in a solid, phonons can have only certain allowed energies. A typical phonon spectrum, which relates the energy of the phonons to their momentum (or wave vector), is shown in Fig. 1. In this

FIG. 1. Phonon spectrum.

Figure, the phonon energy is $\hbar\omega$ and the momentum (or wave vector) is q . There are $3N$ discrete values of q associated with a lattice containing N particles, and the maximum value of q is of the order of (π/a) ($\sim 10^8 \text{ cm}^{-1}$) where a^3 is the volume of a unit cell. (A unit cell is the approximate volume taken up by each molecule of the crystal.) Typical values of the points marked ω_{\max} are 10^{12} to 10^{13} radians/sec.

The two types of phonon branches shown in Fig. 1 (A and O), are the acoustical branch ($\omega = 0$ at $q = 0$) and the optical branch. The motion of the atoms which is represented by the acoustical branch is similar to that which is obtained when a sound wave is propagated in the crystal. The optical branch represents motion in

which the center of mass of the different atoms in a unit cell (or a molecule) remains fixed, but the atoms in the molecule move relative to each other. This type of motion is often excited by an electric field or a light wave, hence the name optical phonon.

Each branch is further divided into longitudinal (L) and transverse (T) modes, again in analogy with propagation of sound waves. In the longitudinal branch, the atoms vibrate in the same direction that the phonon moves, while in the transverse branches, the atoms vibrate perpendicular to the phonon motion. It should be noted that there is a forbidden energy gap between LA and LO which indicates that phonons having these frequencies do not exist in the material.

Several equations which represent the energy content of the phonon modes complete the description. The total energy of each mode q is quantized according to

$$E_q = n_q \hbar \omega_q \quad (1)$$

where n_q is the number of quanta excited at temperature T with frequency ω_q and is given by

$$n_q = [\exp(\hbar \omega_q / kT) - 1]^{-1} \quad (2)$$

where k is Boltzmann's constant. By combining Eq. (1) and (2), we note that at any temperature T , most of the phonons have an energy of about kT , as long as $kT/\hbar < (\omega_q)_{\max}$. The value of $T = (\hbar \omega_q)_{\max} / k$ is approximately θ_D , the Debye temperature.

For completeness, a density term $\rho_j(\omega)$ should be defined. This represents the fraction of phonons of the j th branch which have frequencies between ω and $\omega + d\omega$. However, the form of the distribution is complicated, depending on the symmetry of the lattice and the strength of the restoring forces between atoms. For low-frequency acoustical phonons, in a three-dimensional lattice,

$$\rho_j(\omega) \propto \omega^2 d\omega \quad (3)$$

In any process in which phonons interact with any other particles (or excitations) in the solid, for example electrons, photons, or neutrons, the normal conservation laws must be satisfied. That is, total energy and total momentum must be unchanged. Thus if a phonon is destroyed in an interaction with an electron, the electron must gain an amount of energy $\hbar \omega$ and momentum q which the phonon originally had.

Phonon Interactions and Transport. Many of the thermal properties of solids which are due to the lattice, as distinguished from the electrons, can be obtained using the energy of Eq. (1) in the normal thermodynamic relations. For example, the specific heat C_q due to all the phonons with momentum q is given by

$$C_q = \frac{\partial E_q}{\partial T} = k \left(\frac{\hbar \omega}{kT} \right)^2 \frac{e^{\hbar \omega / kT}}{(e^{\hbar \omega / kT} - 1)^2} \quad (4)$$

To obtain the total specific heat, we simply add up the contributions from each mode q . This

sum is most easily obtained if we know the distribution function $\rho_j(\omega)$ and the value of $(\omega_q)_{\max}$. For example, the Debye theory uses approximate expressions for these quantities and obtains

$$C = 9Nk(T/\theta_D)^3 \int_0^{\theta_D/T} \frac{x^4 e^x dx}{(e^x - 1)^2} \quad (5)$$

where N is the number of atoms per unit volume.

To obtain the heat conductivity in solids, the transport of energy by means of the phonons must be considered. Phonons can be very efficient heat carriers, as indicated by the fact that the maximum thermal conductivity due to electrons in copper is about 50 watts/cm deg as compared to about 200 watts/cm deg due to phonons in pure single crystal sapphire, in which all the heat is carried by phonons.

The heat conducted by the phonons of momentum q is given approximately by

$$\kappa_q \approx \frac{1}{3} C_q v_q l_q \quad (6)$$

The total thermal conductivity is obtained by summing the values of κ_q over all the possible values of q . The mean free path l_q is a measure of how far a phonon travels before it interacts, or is scattered. Phonons can be scattered by impurities and imperfections, by electrons, by other phonons and by the walls of the solid. The mean free path for any of these processes can be determined, to some extent, by examining the temperature dependence of the thermal conductivity.

Another method of investigating the scattering of phonons is through the investigation of the attenuation of very high-frequency sound waves in solids. It is possible to generate "ultrasonic" sound waves with frequencies in excess of 10^9 cps. These correspond to the lowest values of ω shown in Fig. 1 and would be, for example, the majority of the phonons if the sample were held at 0.5 K. In the near future these ultrasonic frequencies will be increased, and more of the phonon spectrum will be investigated using this tool.

The Determination of the Phonon Spectra. The actual values for the ω -vs- q curves which make up the phonon spectrum are obtained in a variety of ways. The value ω_0 of the $q = 0$ optical phonon is related to the infrared Reststrahl frequency. The low q values for the acoustic branches can be obtained by measuring the velocity of transverse and longitudinal sound waves in solids. The values of ω near the zone boundaries ($q \approx \pi/a$) can often be obtained from infrared absorption experiments. However, the most important tool for elucidating the details of the phonon spectrum has been slow neutron scattering. By examining the intensity and position of a scattered neutron beam, a large portion of the ω -vs- q curves can be mapped. Once the ω -vs- q curves have been obtained for a solid, it is possible by mathematical analysis to examine the nature and the magnitude of the forces between the atoms of that particular material. This has been done for a number of materials.

The phonon is of importance to a great many phenomena; electron mobility, optical absorption, electron spin resonance, electron tunnelling, and superconductivity are a few. At the same time, the phonon spectrum represents a detailed picture of the forces which hold solids together. Thus it is clear why the phonon has been and will continue to be of fundamental importance in solid-state physics.

PHOTOCHEMISTRY*

Photochemistry deals in its broadest sense with the phenomena produced by energy-rich photoexcited states.¹ These states, when produced by the absorption of visible or ultraviolet light, are electronically excited states resulting from the transfer of an electron to a higher energy level. The time required for this transfer is so short that the positions of the nuclei of the atoms involved remain unchanged. This primary act is followed the movement of the nuclei to new equilibrium positions and by a great many different kinds of processes such as fluorescence, phosphorescence, degradation of the absorbed energy to heat, the intra- or intermolecular transfer of the electronic energy, or of electrons, protons or hydrogen atoms, or the breaking apart of the energy rich excited species, such as Cl_2 into Cl atoms, O_3 into O_2 and O, the production of a wide variety of ions, radicals, new molecules or chemical reactions. Such reactions are the natural photosynthetic process, photography, the electron transfer reaction in which gaseous hydrogen and oxygen are produced from water by light absorbed by cerium ions in water, photochromism as in the ortho-nitrotoluenes, *cis* to *trans* and *trans* to *cis* isomerization as in the case of the thioindigos, anils and azo compounds, shifting of

the positions of double bonds as occurs when ergosterol is converted into Vitamin D and addition reactions to multiple bonds.

The unit of light energy most useful in photochemistry is the photon, $\epsilon = hc/\lambda$, where h is Planck's constant ($6.5 \cdot 10^{-27}$ erg sec), c is the velocity of light (3×10^{10} cm/sec) and λ is the wavelength of the light, e.g., 6700 Å or $6700 \cdot 10^{-8}$ cm for the most intense light reaching the earth from the sun. Another photochemical unit of light energy is the einstein which is the energy of $6 \cdot 10^{23}$ or one mole, N , of light quanta. Thus one einstein of red light is $N\epsilon = Nhc/\lambda = 6 \cdot 10^{23} \times 6.5 \cdot 10^{-27} \times 3 \times 10^{10}/6700 \times 10^{-8} = 17.5 \cdot 10^{11}$ ergs or $17.5 \cdot 10^{11}/4.186 \cdot 10^7 = 42\,000$ calories or $42\,000/23\,024 = 1.8$ eV. This amount of energy is greater than the energy of activation required to initiate most thermal reactions.

In a narrower sense, photochemistry deals only with the chemical reactions brought about by the absorbed light. This includes studies of the kinetics and mechanisms of reactions such as the mechanism of the reaction between H_2 and Cl_2 to produce HCl. In this case only the Cl_2 molecules absorb visible light and the reaction proceeds mainly as follows:

where X is either H or Cl. The net quantum yield for this chain reaction has been found under favorable conditions to be over one million moles of HCl produced per mole of visible light quanta absorbed by the chlorine molecules.

The natural photosynthetic process converts solar energy into energy available in storage for man's use. One part of the process is the oxidation of water to molecular oxygen by the over-all half reaction:

The other part of the process is the reduction of carbon dioxide to carbohydrate by the over-all half reaction:

The sum of reactions (5) and (6) is the charge and energy transfer process:

which is brought about by sunlight absorbed neither by the water nor the carbon dioxide but by the green substance, chlorophyll, in the proper watery environment.

The production of heat and light by the burning of wood in oxygen is the reverse of reaction (7).

*This is publication No. 90 of the M.I.T. Solar Energy Conversion Project which is supported by the Godfrey Lowell Cabot Fund of the Massachusetts Institute of Technology.

It thus becomes apparent that the energy produced in this way came originally from the sunlight which produced reaction (7) and thereby converted solar energy into energy available in storage for man's use.

The path of oxygen in the natural photosynthetic process has been followed by the use of the oxygen isotope of mass 18 and the path of carbon by the use of the radioactive isotope of mass 14. Very little is known, however, about the way the light absorbed by the chlorophyll brings about the reaction. Studies designed for this purpose would require the identification of all the light-absorbing species, including the transient intermediates, and their absorption spectra and absorbances.

One key to the elucidation of photochemical reactions is the determination of net quantum yields based on the amount of the measured reaction produced by light of nearly uniform intensity absorbed by the species which thereby initiated the measured reaction in an adequately mixed system under nearly equilibrium conditions. Especially helpful is the study of the influence upon the net yields of such variables as light intensity, temperature and the absolute and relative concentrations of the components of the system.

Net quantum yields are usually calculated from gross quantum yields which are based on the amounts of the measured effect and light absorbed by the entire system and on the absorption spectra, absorbances and concentrations of the different light absorbing species. Net quantum yields are evaluated most easily when the light is monochromatic, i.e., when the light consists of a narrow band of wavelengths such as the light of 2537 Å isolated from a low-pressure mercury vapor lamp.² This light, however, needs to be sufficiently intense to produce an appropriate amount of reaction in a convenient length of time.

Another key to the elucidation of photochemical reactions is the employment of flash photolysis made possible by apparatus consisting of a flash source and auxiliary apparatus for studying light absorbing intermediates of lifetimes as short as a few microseconds.²

PHOTOCONDUCTIVITY

Photoconductivity is the increase in electrical conductivity which occurs in a nonmetallic solid when it is exposed to electromagnetic radiation. The conductivity increase is due to the additional

free carriers which are generated when photon energies are absorbed in electronic transitions. The rate at which free carriers are generated and the length of time they persist in conducting states (lifetime) determines the amount of conductivity change.

The absorption transitions and, therefore, the photoconductivity resulting from them are termed intrinsic or extrinsic according to the energy states involved. When the photon energy is at least equal to the forbidden energy gap ($hc/\lambda \geq E_g$), electrons may be excited from the filled band to the conduction band. This intrinsic absorption transition produces an electron-hole pair, an electron in the conduction band and a hole in the valence band. Free carriers may be produced at lower photon energies when there are impurities or other crystal defects which give rise to energy states in the forbidden gap. Such a state is at an energy $E_c - E$ below the conduction band and $E - E_v$ above the valence band. Depending on whether the state is or is not occupied by an electron, a photon of appropriate energy may produce a transition from the state to the conduction band ($hc/\lambda \geq E_c - E$) or from the valence band to the impurity state ($hc/\lambda \geq E - E_v$). The former transition produces a free electron and the latter a free hole.

The carriers so generated are "excess" carriers, i.e., in excess of the number of carriers present in the solid in thermal equilibrium. In equilibrium, in the absence of light, the rate at which free carriers are generated by thermal processes and the rate at which they return to nonconducting ground states (recombination rate) are equal. The density of free carriers remains constant in time, aside from statistical fluctuations. The production of free carriers by absorption of radiation amounts to an increase in the total generation rate of free carriers, unbalancing the equilibrium. The recombination rate is a function of free-carrier density, so it will also increase as the free-carrier density increases. Thus, under steady illumination, there will be a new equilibrium (steady-state) at a new carrier density ($n_0 + \Delta n$), at which the rate of generation of carriers due to absorption (G) is equaled by the increase in the recombination rate (ΔU) due to the increased carrier density (Δn). The steady-state value of Δn is equal to the product $G\tau$ since the lifetime (τ) is equal to $\Delta n/\Delta U$.

The rate of change of excess carrier concentration is described by the equation

$$\frac{d\Delta n}{dt} = G - \frac{\Delta n}{\tau} = G - \Delta U \quad (1)$$

In general τ is not independent of Δn so ΔU is not always simply proportional to Δn . The dependence of τ on Δn is a property of the recombination mechanism. There are a variety of possible recombination mechanisms. Recombination may occur by a direct recombination of a free electron and a free hole or indirectly through a localized energy level (recombination center) which captures a hole and then an electron or

vice-versa. In extrinsic photoconduction, the localized energy state from which the free carrier was excited is, in effect, an immobilized carrier of the opposite type. In this case the recombination kinetics are essentially the same as for direct recombination. Several recombination processes may operate simultaneously. However, in most cases one will have the highest recombination rate and will dominate.

Direct Recombination. In direct recombination the recombination rate is the same for electrons and holes since they recombine in a single process. The total rate is given by

$$U = C(n_0 + \Delta n)(p_0 + \Delta p) \quad (2)$$

where C is the capture probability, n_0 and p_0 are the equilibrium densities of electrons and holes, and Δn and Δp are the excess carrier densities. Δn is equal to Δp since electrons and holes are generated and recombine in pairs. The equilibrium recombination rate is Cn_0p_0 so the excess recombination rate is

$$\Delta U = C(n_0 + p_0 + \Delta n)\Delta n \quad (3)$$

and the lifetime of excess carriers is

$$\tau = [C(n_0 + p_0 + \Delta n)]^{-1} \quad (4)$$

For small signals τ is independent of Δn . However, when Δn is comparable with $(n_0 + p_0)$, this is no longer the case. In insulators (where $n_0 + p_0$ is very small) or for large signals, $\Delta n \gg n_0 + p_0$. This leads to the steady-state relation

$$\Delta n = G\tau = \sqrt{G/C} \quad (5)$$

Recombination Centers and Traps. Indirect recombination through localized centers requires separate equations for electrons and holes, since the recombination rates for electrons and holes are not necessarily equal except in steady state. There are four transitions involved in the kinetics of localized centers: (1) A filled center may capture a hole from the valence band; (2) the electron may be thermally excited to the conduction band; (3) an empty center may capture an electron from the conduction band, or (4) the trapped hole may be excited to the valence band. The rate of capture of electrons by localized centers is given by $C(1-f)n$ where C is the capture probability of the centers for electrons, N is the density of centers, f is the fraction of centers already occupied by electrons, and n is the electron density. The product $(CN)^{-1} = \tau_{n0}$ is the characteristic lifetime due to capture by that center when n is the minority carrier in strongly p -type material. The rate of thermal excitation from the centers is given by $CfNn_0 \exp(-E/kT)$, where N_0 is the effective density of states in the conduction band and E is the thermal ionization energy for the centers. With $N_0 \exp(-E/kT) = n'$, the total capture rate for electrons may be written

$$U_n = \frac{(1-f)n}{\tau_{n0}} - \frac{fn'}{\tau_{n0}} \quad (6)$$

The expression for holes, with equivalent definitions, is

$$U_p = \frac{fp}{\tau_{p0}} - \frac{(1-f)p'}{\tau_{p0}} \quad (7)$$

In thermal equilibrium, these net capture rates are each equal to zero. When n and p are increased (f remaining constant for the moment) the capture rates for electrons and holes increase by $[(1-f)\Delta n]/\tau_{n0}$ and $(f\Delta p)/\tau_{p0}$, respectively. If f is not too nearly equal to unity and $\tau_{p0} \gg \tau_{n0}$, then $(1-f)/\tau_{n0} \gg f/\tau_{p0}$. With Δn and Δp being generated in equal densities, the capture rate for excess holes does not balance that for excess electrons. As a consequence, f must increase; i.e., electrons are trapped. If N is large, then the density of trapped electrons, $N\Delta f$, may be large. On the other hand $(1-f)/\tau_{n0}$ may be comparable to f/τ_{p0} in which case the center may function as an efficient recombination center. If N is not too large, a small amount of trapping may suffice to equilibrate the two capture rates.

The discussion of the basic photoconductive effect above has tacitly assumed uniform material, neutral contacts, and uniformly absorbed photon flux. Nonuniformity of material, either resistivity gradients or p - n junctions, gives rise to observable voltages due to diffusion of photoexcited carriers. This photovoltaic effect is used in solar cells and exposure meters. Nonuniformly absorbed radiation, as will occur when strongly absorbed radiation is absorbed entirely in a thin surface layer on a bulk crystal, will produce a diffusion of photoexcited carriers into the bulk of the crystal. When mobilities are different or trapping is present, a voltage may be detected (the Dember voltage) or, in the presence of a magnetic field, the photoelectromagnetic effect. Even when a photoconductor is otherwise uniform in composition, its surfaces introduce a perturbing influence. For example, the surface may contain a set of very efficient recombination centers, so that lifetime near the surface is much smaller than in the bulk. This will cause a nonuniformity in excess carrier concentration which will not be constant in time (in general). This surface recombination may dominate lifetime in a thin sample, and in a thick sample it may cause a deviation from exponential decay even if the bulk lifetime is independent of Δn .

The phenomenon of photoconductivity is intimately related to semiconductor device phenomena since most devices, e.g., transistors, lasers, luminescent materials, operate by means of non-equilibrium densities of carriers which are subject to the same recombination and trapping kinetics as in photoconductivity.

PHOTOELASTICITY

Photoelasticity is a method of determining stresses or strains in transparent materials by means of polarized light. It is widely used in engineering laboratories for the analysis of stress distributions in models of structures and machine parts. In the majority of problems, the results of such model tests are directly transferable to the metallic prototypes, as long as the materials of the models and prototypes both remain *elastic* (hence the origin of the term).

The *photoelastic effect* can be explained by assuming that an initially plane-polarized light beam, in passing through the stressed plane specimen, breaks up at every point into two components (*birefringence*), corresponding to the directions of the two principal stresses at that point (see POLARIZED LIGHT). The relative retardation between these two components will be proportional to the difference of principal stresses at each point. If the emergent light is passed through a second plane-polarizing unit (the *analyzer*), the principal plane of which is usually put at right angle to the first one, the two relatively retarded components are reduced into one plane and give rise to interference. In general, a number of such interference bands will appear in the model simultaneously, along each of which the principal stress difference (or maximum shear) will be of a constant value, that can be determined by calibration. If white light is used for the source, these bands will appear in the subsequent colors of the spectrum and are thus called *isochromatics*. At points where the incident plane-polarized light happens to coincide with the direction of one of the principal stresses, the light will merely pass through as a plane wave and, subsequently, will be cut out by the crossed analyzer. All such points in the piece will thus be connected with a dark band for any particular inclination of the crossed polarizer and analyzer. These bands are the *isoclinics*, which define the orientation of the principal stresses. They can be eliminated by the use of quarter-wave-plates, which produce circularly polarized light, devoid of the above directional property.

The isochromatics and isoclinics furnish two of the three independent parameters needed to

define the state of stress at any point in a two-dimensional field. The third parameter may be obtained by a variety of supplementary means such as lateral extensometry, mechanical or electrical analogies, or by numerical integration.

The increased use of the photoelastic method was greatly aided by successive improvements in model materials, from glass and celluloids to the latest thermosetting resins, such as the epoxies.

An extension of the method to spatial problems (three-dimensional photoelasticity) provides the only known experimental means for the determination of the state of stress in the interior of solids. The method is also used in dynamic (transient stress) studies, and its scope is extended now into nonelastic fields (photoplasticity and photoviscoelasticity).

PHOTOELECTRICITY

For the purposes of this article, photoelectricity is defined as the emission of electrons resulting from the absorption of radiation in a material. This definition is purposely broad: by radiation, we understand electromagnetic radiation ranging from the shortest wavelength to the longest, from gamma-rays into infrared. The electrons can be released into vacuum or into a second material and the material itself can be either a solid, a liquid, or a gas.

Although there may have been some observations, which with hindsight could be called photoelectric observations, the real history of photoelectricity starts with the work of Hertz. It was in the course of his experiments on electrical resonance that he observed that the length of the spark which could be induced in an auxiliary circuit was greater if the spark gap was irradiated by the ultraviolet light generated by the spark of the primary circuit. He found also that the effect is most marked when the electrode, which is illuminated, is negative. Stimulated by the investigations of Hertz, Hallwachs made a more thorough investigation of the phenomenon, and his work, coupled with that of Elster and Geitel, Lenard, and J. J. Thomson, led to Einstein's

fundamental concept. He pointed out that so far as the photoelectric effect is concerned, light can be regarded as being made up of individual particles, or light quanta, each containing an amount of energy equal to $h\nu$ where h is the constant of Planck and ν is the frequency of the light.

$$h(\nu - \nu_0) = \frac{1}{2}mv_{\max}^2 = eV$$

$$h\nu_0 = e\phi$$

In this formulation of the Einstein photoelectric equation, the maximum kinetic energy of the electron ejected from the material is a function of the frequency of the exciting light minus the frequency of a threshold characteristic for the material. m , e and v are the mass, charge and velocity of the emitted electron, and V is the potential difference required to reduce the velocity of the emitted electron to zero. The quantity $h\nu_0$ is usually called the work function, whereby the work function ϕ is defined as the work necessary to remove to infinity an electron from the lowest free electron state in the metal, W_0 . If the electron is taken from the Fermi level, its work function $\phi = W_0 - W_f$.

Einstein's law predicts that the emission current should be directly proportional to the intensity of the incident light, a statement which underwent numerous critical investigations and was found to be correct. It is also consistent with a three-step model of the photoelectric emission from a solid. In the first step, the photon is absorbed. Absorption may be at any distance from the surface, governed by the light absorption constant of the material. As the emitted electron may be ejected at a finite depth, it has to diffuse through a crystal lattice to the surface and may lose energy in the diffusion process. The third step is the escape of the electron from the solid over a potential barrier.

While the above model is consistent with the Einstein equation, this latter does not predict the entire behavior of the photoemission from a solid. In particular, it does not say anything about the temperature coefficient. A theory was, therefore, necessary, and a quantum mechanical theory was provided by Fowler. On the basis of the initial assumption, that all electrons with normal components of energy greater than ϕ would escape, he established a relationship between the photoelectric current I and the temperature T

$$I = \alpha AT^2 \varphi(x)$$

where α and A are constants and x is defined by

$$x = \frac{h(\nu - \nu_0)}{kT}$$

The function φ is an exponential series, whose numerical values have been tabulated. The Fowler equation allows a very convenient plotting of photoelectric emission results, and the typical Fowler curve is a presentation of logarithm I/T^2 plus a constant vs x . Incidentally, this presentation allows a very convenient and fast determination of the wavelength threshold value, which is equivalent to the work function for the material.

The detailed remarks of the last two paragraphs are essentially limited to the photoelectric effect in pure metals and the ejection of the electron into vacuum. Most work functions are relatively high, with a resulting threshold in the ultraviolet region. ϕ ranges in metals from 1.9 eV (7000Å) for Cs to about 5.4 eV (2300Å) for Pt. Quite a bit of effort was made for many years to create photoemitters with low work functions for practical applications in the visible part of the spectrum or even in the infrared. One group of substances, offering considerably lower values than those of the metals, are semi-conductors. While in a metal the photoelectrons originate in the conduction band relatively close to the Fermi level, in semi-conductors they originate in the valence band or in impurity states. If the latter are more favorably placed than the Fermi level, a corresponding reduction of the work function may result. For instance, in Ag-O-Cs ϕ equals 1.0 eV (12300Å). It was found that intermetallic compounds of the I-V or II-V type, such as Cs₃Sb or Na-K-Cs-Sb, offer great advantages.

Observations in the early days of photoelectric research have shown that surface conditions may modify considerably the photoemissive properties of surfaces. The most commonly occurring surface impurity is an oxide layer, and for practical applications fortunately it was found that oxidation often enhances the photoelectric current. Although the mechanism of the photoemission of such surfaces is sometimes very complicated, part of the reason can be found in the enhanced light absorption (reduced reflection) of the photoelectric surface.

Practical application of surface photoemission in the early days was largely limited by the very weak currents which can be obtained from substances with a low efficiency of photoelectric emission. This led to schemes of charge multiplication which produce higher currents. A first such scheme used collision-ionization in a gas. Within a reasonable limit, the so-called gas-filled photocells show a very linear behavior with intensity. In the last 20 years, gas-filled photocells have been almost entirely replaced by photomultipliers, i.e., combinations of photocathodes with secondary electron multipliers. In these latter devices, the multiplication factor may vary from 10^4 to 10^7 .

With increasing attention to the far-ultraviolet range of the spectrum, a few metals with higher work functions find favor as applied devices. In some modern applications, advantage is taken of the insensitivity of a high work function photocathode to visible light. Its response is limited to far-ultraviolet light alone, in the so-called solar-blind type cell.

The second important group of phenomena, which has found many important practical applications, is that in which the ejected electron may travel through the emitting material, to enter a solid electrode in contact with the photoemitter instead of going to the anode through a vacuum. There are two subgroups: one is photoconductivity which is treated elsewhere in this volume, and the second is a group that bears the generic

name of photovoltaic effects. This name is generally applied to the phenomena leading to the direct conversion of a part of the energy absorbed from the impinging photons into usable electrical energy. Most common examples are selenium cells, the barrier-layer-type copper oxide cells, and the so-called solar batteries or solar photovoltaic converter, consisting usually of a semiconductor crystal like silicon containing a composition gradient termed the *p-n* junction. These last devices have now reached a relatively high grade of efficiency where up to 15 per cent of the energy of the incident light may be converted into electric current. Theoretically, 50 per cent efficiency might be obtained in a three-semiconductor sandwich assembly.

Photoelectric effects in liquids and in gases are essentially of the photoconductive type.

PHOTOGRAPHY

The history of photography spans over more than a century and embraces many techniques for producing photographic images. Within the past year or two alone, a number of important innovations have been made in photographic recording.

Although there is great diversity in image-forming optical systems, photosensitive materials, and development procedures, some form of each is essential to every photographic process. Light from the subject passes through the optical system or camera, and impinges on the photosensitive material to form a latent or invisible image. The latent image is transformed by chemical or physical means into a visible negative or positive image.

Most photographic processes use mixtures of silver halides (silver chloride, bromide, and iodide) as the photosensitive materials. These processes include conventional black and white photography and color photography, "Polaroid" black and white photography, and such recent innova-

tions as "Polacolor," three-dimensional color photography, and lensless photography. A number of other photographic processes are based on photochemical reactions of organic dyes and of inorganic metal salts other than silver halides. Still other processes employ light-induced changes in the physical properties of materials such as photoconductors or thermoplastics.

In conventional silver halide photography, the camera consists of a lightproof box with a lens for admitting and focusing the light, a diaphragm for controlling the size of the effective lens aperture, a shutter for regulating the length of exposure and the photosensitive film.

Two recent developments in photography are based on unconventional image-forming systems. In lensless photography¹, monochromatic light from a laser is split into two beams, one of which enters the lensless camera directly, while the other enters after passing through a transparent image. The two beams combine to form a Fresnel diffraction pattern of the image which is recorded on film. This recorded pattern is called a hologram. To reconstruct the image, a beam of laser light is transmitted through the hologram to generate a second diffraction pattern, a component of which reproduces the original image onto the screen.

The other new process is for mass producing a "three-dimensional" photograph known as a parallax panoramagram on a two-dimensional card.² The picture is coated with a plastic layer composed of vertical rows of cylindrical lenses which give the illusion of depth.

Ordinary photographic film is a suspension of microscopic silver halide crystals³ in gelatin coated on a supporting layer. Gelatin is a stable porous medium which allows the processing solutions to reach the dispersed crystals. Gelatin contains impurities which produce sensitivity centers. These are tiny silver sulfide centers of at least ten molecules each, which form on the surface of the crystals and catalyze the formation of the latent image by light.³

When the film is exposed, the following reaction takes place:

The latent image consists of small specks of metallic silver on the silver halide crystals. The smallest latent image speck that can make an exposed crystal develop during processing has from four to ten atoms. Not all absorbed photons contribute to this latent image. Assuming that a typical speck of ten atoms formed by absorbing one hundred photons can cause development of a crystal with 10^{10} ion pairs, the amplification factor is about 10^8 , which is higher than that of any other photographic material.

The developer reduces silver ions in the exposed crystals to silver atoms which deposit on the specks. The unexposed crystals are removed from the emulsion by a "fixing" solution to form the negative. A positive print is obtained by

exposing an emulsion-coated paper to white light through the negative and developing it.

In the "Polaroid" process developed by E. H. Land,³ a positive print is obtained directly from the camera one minute after exposure. The negative emulsion layer is pressed against a non-sensitive layer of paper between metal rollers in the camera. Sacs containing a viscous developer are ruptured as the two strips are pressed together, squeezing the developer uniformly between the strips. The developer develops the negative image, then dissolves the unexposed crystals and transfers them to the paper layer which contains dry developer to develop the positive print.

Silver halide emulsions are sensitive to ultraviolet and visible light with the maximum response in the blue at about 4200Å. Their range can be extended to any wavelength up to 12 000Å in the infrared by sensitizing dyes which absorb light in the desired spectral regions and transfer the energy to the crystals. The latent image is then formed in the usual way. Two common sensitized emulsions are panchromatic film (6200Å), and orthochromatic film (5600Å).

In modern color photography, integral tripack films are usually used. An integral tripack is a film of three sensitive layers separated by gelatin. Each layer contains crystals sensitized to one of the primary colors for light mixing, i.e., red, green, or blue. After exposure the three silver negatives in the nonseparable multilayered film are developed.

The most common method of forming the dye image is the dye coupling process. During development of the silver negative, the developer is oxidized in proportion to the silver reduced. The oxidized developer reacts or "couples" with a chemical to form a dye which produces a negative color image. A cyan dye in the red sensitized negative absorbs red light, while the blue sensitized emulsion acquires a yellow dye and the green sensitized emulsion a magenta dye. The superposition of the three color negatives then transmits the colors complementary to those of the original image.

To make color prints the colors are reversed by exposing a three layer emulsion on paper to white light through the color negative. To make positive transparencies the color reversal is performed directly on the three emulsion layers by changing the development procedure.

The remarkable "Polacolor" process recently developed by E. H. Land produces a color print fifty seconds after exposure¹ instead of the hour and a half required for the conventional process. The camera and the mechanical operations are similar to those for "Polaroid" black and white photography.

One innovation in this process is a new type of molecule with a preformed dye on one end and a developer on the other. The dye-developer linked molecules are placed inside the negative which is an integral tripack. After exposure the viscous reagent liberated from the pods sets the linked molecules in motion. Those that hit an exposed crystal in the appropriately sensitized emulsion

become fixed to the crystal site during development and form a negative color image. The other linked molecules move until they enter the positive which is pressed against the negative in the camera. The positive is a silver halide emulsion exposed together with the negative. The linked molecules containing the three types of dyes develop the exposed crystals to form the positive color print.

Photographic processes using photochemical systems other than silver halides have lower light sensitivity, but may be used to achieve special effects.⁵

A class of processes known as electrophotography uses materials which show an increase in electrical conductivity during light exposure. Electrophotography is widely used for office copying machines and for continuous tone photography.

In one type of electrophotography, charges are sprayed on a selenium or zinc oxide layer by a corona wire charged to five or ten thousand volts.³ During exposure, the charges leak off imagewise through the photoconductive layer. The remaining charge pattern is the latent image which is developed by applying an oppositely charged black resin powder which adheres to the charged areas. The image is fixed by slight heating to fuse the resin. "Electrofax" and "Xerography" are commercial adaptations of this process.

A type of electrophotography based on the "persistent internal polarization" effect in photoconductors promises to be even more useful.⁶ A potential of a hundred volts is applied across a zinc sulfide layer during exposure. Electrons in exposed regions are pulled toward the positive electrode and trapped en route by impurity atoms. The latent image is the imagewise internal polarization due to separation of trapped negative and positive charges. It is developed with the charged resin. This process has not yet been commercially exploited, although a few office copying machines have been built. However, it has several advantages over the other type of electrophotography, since the charging potential is much lower and the internal charges persist for a very long time. Negative or positive images may be made with equal ease. This process has been used to record wavelengths up to 20,000 or 30,000Å in the infrared where silver halides are not sensitive.

Thus, the past few years have brought about important innovations in silver halide and other photographic processes, and by extrapolation the future promises even greater wonders.

PHOTOMETRY

Photometry is concerned with the measurement of light, or much more frequently, of the time rate of flow of light. Light is the aspect of radiant energy to which the human eye responds, or more precisely it is Q_v in the equation:

$$Q_v = K_m \int V(\lambda) Q_{e,\lambda} d\lambda$$

in which K_m is the maximum luminous efficacy of radiant energy (about 680 lumens/watt), $V(\lambda)$ is the CIE (International Commission on Illumination) spectral luminous efficiency function¹ which is curve 4 of the figure shown in the article on COLOR in this Encyclopedia, and $Q_{e,\lambda}$ is the spectral distribution of radiant energy.

The quantities with which photometry is concerned are luminous intensity and flux, illuminance and LUMINANCE, and luminous reflectance and transmittance.

The devices which are used to measure these quantities are called photometers. They fall into two general categories, namely, visual and physical. The making of brightness matches is a requisite in the use of visual photometers, while in physical photometers, which are usually of the photoelectric or thermoelectric type, luminous energy incident on a receiver is transformed into electric energy and the latter is measured by means of sensitive electric meters or devices. In visual photometry, observers with so-called normal color vision are used, it being tacitly assumed that the average spectral response of the observers used to make the observations approximates the standard CIE luminous efficiency curve. In physical photometry, the receiver should be equipped with a filter, the spectral transmittance of which when multiplied by the relative spectral response of the receiver, wavelength by wavelength, closely approximates the CIE luminous efficiency curve. In all photometric measurements which involve differences between the spectral distribution of the standard source used to calibrate the photometer and that of the test source, the accuracy of the results obtained is dependent on the degree of approximation of the spectral response curve of the photometer to the CIE spectral luminous efficiency curve.

The unit of luminous intensity (often called candlepower) is the candela. Its magnitude is

such that the luminous intensity of one-sixtieth of one square centimeter of projected area of a blackbody at the freezing point of platinum² is one candela. Such a blackbody has been the international standard of light since January 1, 1948. National standardizing laboratories, like the National Bureau of Standards in the United States, calibrate incandescent-lamp reference standards of luminous intensity in terms of the international standard. The calibration for luminous intensity of other incandescent lamps relative to these reference standards or to other standards of luminous intensity is usually done on a bar photometer, which consists of a horizontal bar equipped with movable carriages, on one of which the standards and lamps to be calibrated are mounted in turn, while the photometric measuring device is mounted on the other carriage. The calibration involves the use of the inverse-square law which states that the illuminance at a point on a surface varies directly with the luminous intensity I of the source and inversely as the square of the distance d between the source and the point on the surface. If the surface at the point is perpendicular to the direction of the incident light, the law may be expressed as follows: $E \propto I/d^2$. In the measurement of the intensity I_2 of a source relative to the intensity I_1 of a standard, the illumination at the photometer from the two sources is made equal by varying the distance d , so that $I_2 = I_1 d_2^2/d_1^2$ in which d_2 and d_1 are the distances for the unknown and standard, respectively. The important precautions which must be taken in calibrating and using standards of luminous intensity are (1) that the distance between the standard and photometric receiver is sufficiently large relative to the size of the source and of the receiver so that the source and receiver act approximately as points,³ (2) that the standard is accurately oriented with respect to the receiver,⁴ and (3) that by the use of baffles no flux is incident on the receiver other than that which comes directly from the standard.

Illuminance is incident luminous flux per unit area. In the measurement of illuminance, a photometer, in this application often called an illuminometer, is used. The illuminometer is calibrated at n points by the use of a standard of luminous intensity I placed at n distances d from the test plate of a visual photometer or the surface of the receiver, thus yielding n illuminances E computed from the inverse-square law $E = I/d^2$. It is important that the geometric characteristics of the receiver of the illuminometer be such as to enable it to evaluate, without bias, luminous flux which is incident on the receiver from all directions; special precautions are usually necessary if flux incident at large angles to the perpendicular to the receiver is to be properly evaluated.

The unit of luminous flux is the lumen which is defined as the luminous flux in a unit solid angle (steradian) from a point source having a uniform intensity of one candela. Standards of luminous flux are calibrated in terms of standards of luminous intensity by the use of a two-step procedure. In one step, the luminous intensity in a specified

direction of the lamp to be calibrated is determined, and in the other step, by the use of a distribution photometer, the relative luminous intensity of this lamp in a multiplicity of directions is determined. To enable one to see how each of these intensities is effective in contributing luminous flux, one notes that each direction intersects a hypothetical sphere circumscribed about the lamp and that around the point of intersection on the sphere surface an area can logically be assigned which defines the solid angle in which the luminous intensity in that direction is effective in supplying luminous flux. These solid angles in steradians, by which the luminous intensity values must be multiplied to obtain the lumens incident on the respective areas, are called zonal constants. Such constants for various patterns of distribution measurements have been published and are thus readily available.^{5,6} Reference standards of luminous flux are calibrated by this procedure, but other standards are calibrated in terms of the reference standards or of other standards of luminous flux by the use of an integrating sphere, sometimes called an Ulbricht sphere. It is a spherical hollow enclosure with a uniform, diffusely reflecting inner surface. In such an enclosure, the illuminance due to reflected flux is the same at every point on the surface and is directly proportional to the flux emitted by a source in the sphere, independent of its angular distribution. The ratio of the fluxes emitted by two sources is thus the ratio of the illuminances at any point on the sphere surface which is shielded from receiving flux directly from the sources. The principal precautions in the use of spheres are (1) that the inner surface be a good diffuser, uniform in reflectance from point to point, and (2) that the spectral selectivity of the sphere throughout the visible region of the spectrum (0.4 to 0.7 μ) be compensated. This compensation is usually accomplished by the use of filters, but another procedure is to disperse the flux from the sphere wall by means of a prism and insert in the spectrum thus formed a template whose shape compensates for both the spectral selectivity of the sphere and the spectral response of the receiver.⁷ It must be remembered that the effect of the spectral selectivity is greatly amplified because of the interreflections within the sphere so that the illuminance on the sphere wall by reflection only is $\rho/(1 - \rho)$ times the average illuminance by directly incident flux, where ρ is the reflectance of the sphere wall; thus if the reflectances at two wavelengths are, for example, 0.80 and 0.72, the spectral irradiance by reflection only at the wavelength of lower reflectance will be only 64 per cent of that at the wavelength of higher reflectance.

There are two related systems of units of luminance which have been and are still being used. In one of these systems the luminance is expressed in terms of luminous intensity per unit projected area or in terms of luminous flux per unit solid angle and unit projected area. The other system is that in which luminance is expressed in terms of the flux per unit area which would leave a

perfect diffuser having the same luminance; the lambert and footlambert are units of this system and their magnitudes are such that one lumen per square centimeter and per square foot, respectively, would leave a perfect diffuser of unit luminance. Standards of luminance are usually combinations of luminous intensity standards and surfaces of known directional transmittance factor or directional reflectance factor (see below). The product of the illuminance of a surface by the appropriate one of these factors gives its luminance; for example, for each lumen per square centimeter incident perpendicularly on a freshly prepared surface of MgO, the luminance at an angle of 45° from the perpendicular will be approximately one lambert because the directional reflectance factor of MgO for this geometry is approximately 1.00. In lieu of the MgO surface, use is more generally made of a highly diffusing glass or plastic plate of known directional transmittance factor for perpendicular incidence on one side of the plate and perpendicular viewing on the other side. The measurement of luminance relative to a luminance standard by visual photometry introduces no serious problems other than those inherent in photometry generally, because the receptor, in this case the eye, intercepts flux in a very small solid angle which can, for all practical purposes, be considered to be infinitesimally small. In physical photometry, however, because of the need to collect flux in an amount which will result in adequate sensitivity, the solid angle of reception is relatively large and cannot in general be considered to be infinitesimally small, so that there is introduced into the measurements an inaccuracy whose magnitude is related to the magnitude of the variation of the flux per infinitesimal solid angle within the solid angle of reception.

In addition to the measurement of the dimensional quantities discussed above, photometry is concerned with the measurement of the dimensionless quantities transmittance, directional transmittance factor, reflectance, and directional reflectance factor. Transmittance and reflectance are the ratio of transmitted and reflected flux, respectively, to incident flux. For a nondiffusing specimen, the measurement of transmittance or reflectance usually poses no great problem. For a diffusing specimen, the measurement of totally diffuse transmittance or reflectance (reception over a solid angle of 2π steradians) for specified modes of illumination of the specimen is usually made with instruments that incorporate integrating spheres;⁸ for solid angles of reception smaller than 2π steradians, the measurement of the ratio of transmitted or reflected flux to incident flux yields what is designated as fractional transmittance or fractional reflectance, respectively, quantities which generally are not of as much interest as are the directional transmittance factor and the directional reflectance factor (usually in the United States widely but inappropriately called directional transmittance and directional reflectance). These factors are defined as the ratio of the flux transmitted (or

TABLE 1. PHOTOMETRIC AND RELATED RADIOMETRIC QUANTITIES, DEFINING EQUATIONS, UNITS AND SYMBOLS

Quantity*	Symbol*	Defining Equation	Unit	Symbol

 † Should be deprecated in favor of emitted luminous exitance.
 *** Φ_i = incident flux; Φ_a = absorbed flux; Φ_r = reflected flux; Φ_t = transmitted flux.

reflected) in the solid angle of interest to that which would be transmitted (or reflected) by the ideal perfect diffuse transmitter (or reflector) identically illuminated; the ideal perfect diffuse transmitter (or reflector) is one which transmits (or reflects) all of the luminous flux incident on it in accord with the Lambert cosine law, i.e., so that the flux per unit solid angle in any direction from it varies as the cosine of the angle between that direction and the perpendicular to the transmitter (or reflector). For a solid angle of reception of 2π steradians, the term directional transmittance (or reflectance) factor is synonymous with transmittance (or reflectance). For infinitesimal solid angles of reception and nonfluorescing specimens, the term directional transmittance (or reflectance) factor is synonymous with luminance factor which for any specimen is defined as the ratio of the luminance of the specimen to the luminance of a perfect diffuser identically illuminated.

The most commonly used photometric and related radiometric quantities, their defining equations and units, and symbols for them which are consistent with those agreed upon to date by the International Commission on Illumination, the International Electrotechnical Commission, the International Standards Organization, and the Commission for Symbols, Units, and Nomenclature of the International Union of Pure and Applied Physics are listed in Table 1.

PHOTOMULTIPLIER

Photomultipliers make use of the phenomena of photoemission and secondary-electron emission in order to detect very low light levels. The electrons released from the photocathode by incident light are accelerated and focused onto a secondary-emission surface (called a dynode). Several electrons are emitted from the dynode for each incident primary electron. These secondary electrons are then directed onto a second dynode where more electrons are released. The whole process is repeated a number of times depending on the number of dynodes. In this manner, it is possible to amplify the initial photocurrent by a factor of 10^8 or more in practical photomultipliers. It is, therefore, evident that the photomultiplier represents an extremely sensitive detector of light.

The major characteristics of the photomultiplier with which the user is generally most concerned are as follows:

- (a) sensitivity, spectral response, and thermal emission of photocathodes;
- (b) amplification factor;
- (c) noise characteristics and the signal-to-noise ratio.

Sensitivity, Spectral Response, and Thermal Emission of Photocathodes. Many different types of photocathodes are being used in photomultipliers. With a selection of various cathodes, it is possible to cover the range of response from the soft x-ray region (approximately 5 to 500Å) to the near infrared (approximately 12,000Å). Photocathodes in common use are listed in Table 1. Typical spectral response curves are shown in

TABLE 1. CHARACTERISTICS OF COMMON PHOTOCATHODES

Fig. 1. The thermal emission at 25°C of CuI and CsI is lower than that of the other cathodes listed, however no quantitative measurements have as yet been published for them.

Amplification Factor. The amplification factor in a photomultiplier depends on the secondary emission characteristics of the dynode and to some extent on the design of the multiplier structure.

Most secondary-emission surfaces used in commercial photomultipliers fall into two classes:

(1) Alkali metal compounds, e.g., cesium antimony.

(2) Metal oxide layers, e.g., magnesium oxide on silver-magnesium alloy.

The alkali metal compounds have higher gain at low primary electron energy (of the order of 75 V). The metal oxide layers show less fatigue at high current density of emission (i.e., at several microamperes per square centimeter or higher).

Table 2 lists some characteristics of the common dynode surfaces.

TABLE 2. CHARACTERISTICS OF COMMON DYNODE SURFACES

Surface	Maximum Secondary Emission Ratio	Primary Voltage for Maximum Ratio
Cs-Sb	8.0	500
Cs-Ag-O	5.8-9.5	500-1000
MgO (on AgMg)	9.8	500

FIG. 1. Spectral response characteristics.

The multiplier structures may be divided into two main types, dynamic and static.

The dynamic multiplier in its simplest form consists of two parallel dynode surfaces with an alternating electric field applied between them. Electrons leaving one surface at the proper phase of the applied field are accelerated to the other surface where they knock out secondary electrons. These electrons in turn are accelerated back to the first plate when the field reverses, creating still more secondary electrons. Eventually the secondary electrons are collected by an anode placed in the tube; if they are not, a self-maintained discharge occurs. In practice, dynamic multipliers have been replaced by static ones mainly because the latter have better stability and are easier to operate.

The static multipliers may be either magnetically or electrostatically focused.

Figure 2(A) illustrates one type of multiplier structure using *magnetic* focusing. Primary electrons impinging on one side of a dynode cause the emission of secondary electrons from the opposite side. These electrons are then focused onto the next dynode by means of the axial magnetic field.

Figures 2(B) through (F) illustrate the more

common types of *electrostatic* multiplier structures. The structures shown in Fig. 2(B), (C), and (D) actually use focusing from one stage to the next. The structures in Fig. 2(E) and (F) are unfocused.

Recent technology has made possible the deposition of thin semiconductor secondary emission surfaces onto insulating substrates. Such dynode strips have been used in designing rugged miniature multiplier structures. Two such structures are shown in Fig. 2(G) and (H). In both these structures the secondary electrons are accelerated along the length of the dynode strip by means of the potential applied across the strip. The structure in Fig. 2(H) can be made particularly small, the dimensions of a typical unit being 0.5 mm outside diameter and 10 mm long.

The unfocused electrostatic structures have less sensitivity to stray electric and magnetic fields. The focused structures, especially (C) and (D) in Fig. 2, can be made to have very short transit-time spreads. Often special accelerating electrodes are placed between the dynodes to improve their transit-time spread and space-charge characteristics. At 200 to 300 V/stage, the transit time spread may be less than 10^{-9} second, and peak

FIG. 2. Various multiplier structures.

pulse outputs of the order of 200 mA may be drawn before nonlinearity owing to space-charge saturation sets in.

In the normal operating range, the over-all amplification G of the multiplier is proportional to V^β , where V is the over-all voltage and β is a constant of the order of seven for a ten-stage structure.

Noise Characteristics and the Signal-to-noise Ratio. It is necessary to distinguish between two types of noise in photomultipliers, dark and shot noise.

The *dark noise* in photomultipliers is caused mainly by the following:

- (1) leakage current across insulating supports,
- (2) field emission from electrodes,
- (3) thermal emission from the photocathode and dynodes,
- (4) positive ion feedback to the photocathode, and
- (5) fluorescence from dynodes and insulator supports.

By careful design and construction of the photomultiplier it is possible to limit the dark noise principally to item (3).

Associated with the photocurrent from the photocathode is *shot noise*. There is also shot noise from secondary emission in the multiplier structure. The mean-square shot noise current $\overline{i_n^2}$ at the anode is given to a close approximation by

$$\overline{i_n^2} = 2ebG^2\overline{i_p}\Delta f$$

where e is the electronic charge, G is the amplification, $\overline{i_p}$ is the average photocurrent, Δf is the bandwidth of the system, and b is a factor equal to approximately 1.5 which accounts for the shot noise created in the multiplier. The signal-to-noise ratio S/N is then given by

$$S/N = \frac{G\overline{i_p}}{\sqrt{\overline{i_n^2}}} = \sqrt{\frac{\overline{i_p}}{2eb\Delta f}}$$

Uses of Photomultipliers. One of the major uses of photomultipliers is in the scintillation counter where in combination with a fluorescent material it is used to detect nuclear radiation. The advent of the space program has led to applications in star and planet tracking for guidance systems as well as in star photometry and quantitative measurements of soft x-rays in outer space. Other applications include use in facsimile transmission, spectral analysis, automatic process control, and many other areas where extremely low light levels must be detected.

PHOTON

The photon is the quantum of the electromagnetic field. It is a particle with zero rest mass and spin one. For a photon moving in a specific direction, the energy E and momentum p of the particle are related to the frequency f and wavelength λ of the field by the Planck equation $E = hf$ and the de Broglie equation $p = h/\lambda$. As for all massless particles, the energy and momentum are related by $E = cp$ and the photon can only exist moving at light velocity c . Another property of all massless particles is this: given the momentum, the particle can exist in just two states of spin orientation. The spin can be parallel or antiparallel to the momentum but no other directions are possible. The photon state with the spin and momentum parallel/antiparallel is said to be right-/left-handed and is a right-/left-hand circularly polarized wave. In analogy with the neutrino, one can say that the state has positive/negative helicity and can call the right-handed particle the antiphoton, the left-handed particle the photon. There is an operation, CP conjugation, that converts a photon state into an antiphoton state and vice versa. It is possible to superpose photon and antiphoton states in such a way that the superposition is unchanged by CP conjugation and so gives a type of photon that is its own antiparticle. The photons produced by transitions between states of definite parities in atoms or nuclei are their own antiparticles in this sense. As for all particles with integer spin, the photon follows Bose-Einstein statistics. This means that a large number of photons may be accumulated into a single state. Macroscopically observable electromagnetic waves, such as those resonating in a microwave cavity for example, are understood to be large numbers of photons all in the same state. The photon, among all the particles, is unique in having its states be macroscopically observable this way.

The electric and magnetic fields \mathbf{E} and \mathbf{B} describe the state of the photon and make up the wave function of the particle. Maxwell's equations give the time development of the fields and take the place, for the photon, that Schrödinger's equation takes for a material particle. Many of the remarks above follow as direct consequences of Maxwell's equations. In Gaussian units, where both \mathbf{E} and \mathbf{B} are measured in gauss or dynes per

electrostatic unit of charge, the equations are

$$\epsilon_{jkl}\partial E_l/\partial x_k + c^{-1}\partial B_j/\partial t = 0 \quad (1)$$

$$\epsilon_{jkl}\partial B_l/\partial x_k - c^{-1}\partial E_j/\partial t = 0 \quad (2)$$

$$\partial E_j/\partial x_j = \partial B_j/\partial x_j = 0 \quad (3)$$

The particle aspect of the equations becomes evident when the equations are written in terms of the complex three-vector

$$\psi_j = E_j + iB_j \quad (4)$$

in which case they become

$$\epsilon_{jkl}\partial\psi_l/\partial x_k - ic^{-1}\partial\psi_j/\partial t = 0 \quad (5)$$

$$\partial\psi_j/\partial x_j = 0 \quad (6)$$

Equation (6) is to be considered as an initial condition rather than as an equation of motion since it follows from Eq. (5) that

$$c(\partial\psi_j/\partial x_j)/\partial t = -ic\epsilon_{jkl}\partial^2\psi_l/\partial x_j\partial x_k = 0$$

so if $\partial\psi_j/\partial x_j$ is zero at the start, it is zero forever. Equation (5) can be cast into Hamiltonian form. One writes the three components ψ_j as a column matrix ψ and introduces three, three-by-three matrices by

$$(s_k)_{jl} = i\epsilon_{jkl} \quad (7)$$

With this notation, Eq. (5) becomes

$$-ic(s_k)_{jl}\partial\psi_l/\partial x_k = i\partial\psi_j/\partial t$$

or

$$H\psi = i\hbar\partial\psi/\partial t \quad (8)$$

where

$$H = c\mathbf{s} \cdot \mathbf{p} \quad (9)$$

and \mathbf{p} is $-\hbar\nabla$. The Hamiltonian for the photon is thus $c\mathbf{s} \cdot \mathbf{p}$. In detail, the matrices that occur here are

$$s_1 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -i \\ 0 & i & 0 \end{pmatrix}, \quad s_2 = \begin{pmatrix} 0 & 0 & i \\ 0 & 0 & 0 \\ -i & 0 & 0 \end{pmatrix}, \quad (10)$$

$$s_3 = \begin{pmatrix} 0 & -i & 0 \\ i & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}$$

They are Hermitian and, as is easily verified, they fulfil the commutation rules

$$[s_i, s_j] = i\epsilon_{ijk}s_k$$

and so are a set of angular momentum matrices. Evidently each has eigenvalues 0, ± 1 so they are a representation of spin one.

Next consider the plane wave solutions. Let them be propagating in the 3-direction; so substitute

$$\psi = u \exp [i\hbar^{-1}(p_3z - Wt)]$$

into Eq. (8). Here the same symbol p_3 is used for the eigenvalue as for the operator. This reduces

to the eigenvalue problem

$$c \begin{pmatrix} 0 & -ip_3 & 0 \\ ip_3 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} u = Wu$$

The eigenvalues are found to be $W = 0, \pm cp$, where p is $|p_3|$, and the corresponding eigenvectors are

$$u_0 = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}, \quad u_{\pm} = \frac{1}{\sqrt{2}} \begin{pmatrix} \pm p_3/p \\ i \\ 0 \end{pmatrix}$$

The $W = 0$ possibility does not satisfy the initial condition, Eq. (6), and so must be discarded. The solutions u_{\pm} are valid for either sign of p_3 ; choose $p_3 = \pm p$ so both waves are propagating in the positive z direction. The two solutions of the problem are then

$$\psi_{\pm} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 \\ i \\ 0 \end{pmatrix} \exp [\pm i\hbar^{-1}p(z - ct)] \quad (11)$$

The subscript \pm denotes that these are eigenstates of the helicity operator $\mathbf{s} \cdot \mathbf{p}/p$ with eigenvalues ± 1 . The electric and magnetic fields are the real and imaginary parts:

$$E_{\pm, x} = 2^{-1} \cos [p\hbar^{-1}(z - ct)] \quad (12a)$$

$$E_{\pm, y} = \mp 2^{-1} \sin [p\hbar^{-1}(z - ct)] \quad (12b)$$

$$B_{\pm, x} = \pm 2^{-1} \sin [p\hbar^{-1}(z - ct)] \quad (12c)$$

$$B_{\pm, y} = 2^{-1} \cos [p\hbar^{-1}(z - ct)] \quad (12d)$$

$$E_z = B_z = 0 \quad (12e)$$

Here it is seen that the \pm helicity solution is right- left-hand circularly polarized with respect to the propagation direction.

The allowed states of the photon are eigenstates of the Hamiltonian H with eigenvalues $\pm cp$. Let $|H\rangle$ be the operator which, applied to the same states, gives eigenvalue cp . The operators for the physical energy, momentum, and angular momentum of the photon are $|H\rangle$, $(H/|H|)\mathbf{p}$, and $(H/|H|)(\mathbf{x} \times \mathbf{p} + \hbar\mathbf{s})$. One can understand these assignments for the energy and momentum by considering the plane wave states of Eq. (11). The states are eigenstates of the operators with energy eigenvalue cp and with momentum eigenvalue p in the positive z direction. As further justification for these operator assignments, the expectation values of the operators are directly related to the classical formulas for energy, momentum, and angular momentum in the electromagnetic field:

$$\int d^3x \phi^\dagger |H| \phi = (8\pi)^{-1} \int d^3x (E^2 + B^2) \quad (13a)$$

$$\int d^3x \phi^\dagger (H/|H|) \mathbf{p} \phi = (4\pi c)^{-1} \int d^3x (\mathbf{E} \times \mathbf{B}) \quad (13b)$$

$$\int d^3x \phi^\dagger (H/|H|) (\mathbf{x} \times \mathbf{p} + \hbar\mathbf{s}) \phi = (4\pi c)^{-1} \int d^3x \mathbf{x} \times (\mathbf{E} \times \mathbf{B}) \quad (13c)$$

where the function ϕ is defined by

$$\phi = |8\pi H|^{-1} \psi \quad (14)$$

These results apply for any solution ψ of Eqs. (6) and (8). The operation $|8\pi H|^{-1}$ in Eq. (14) is to be carried out by expanding ψ in plane wave components like ψ_+ and replacing $|8\pi H|^{-1}$ by $(8\pi c p)^{-1}$ in each component. Proofs of Eqs. (13) will not be given here; they can be made by expressing each side of the equations in terms of the plane wave expansion coefficients. Accepting these operator assignments, one sees that the helicity operator $\mathbf{s} \cdot \mathbf{p}$ is the component of the spin of the photon in the direction of its momentum.

The CP conjugation operation is related to the space reflection covariance of Maxwell's equations. Consider a primed and an unprimed coordinate system such that the coordinates of any point in space referred to the two axes are related by $\mathbf{x}' = -\mathbf{x}$. Suppose the electric field is axial and the magnetic field is polar so that the functions describing the fields are related by $\mathbf{E}'(\mathbf{x}', t) = \mathbf{E}(\mathbf{x}, t)$ and $\mathbf{B}'(\mathbf{x}', t) = -\mathbf{B}(\mathbf{x}, t)$. It is evident that Maxwell's equations have the same form in both coordinate systems and that the transformation rule for ψ is $\psi'(\mathbf{x}', t) = \psi^*(\mathbf{x}, t)$ where the asterisk denotes the complex conjugate. The fact that the equations have the same form in both systems implies further that if $\psi(\mathbf{x}, t)$ is any solution then $\psi'(\mathbf{x}, t)$, or equivalently $\psi^*(-\mathbf{x}, t)$, is also a solution. The operation that carries $\psi(\mathbf{x}, t)$ into $\psi'(\mathbf{x}, t)$ is called CP conjugation and one writes

$$\psi^{CP} = KP\psi \quad (15)$$

where K is the operation "take complex conjugate" and the operator P changes \mathbf{x} into $-\mathbf{x}$. If ψ is a solution of Maxwell's equations so also is ψ^{CP} . However KP anticommutes with $\mathbf{s} \cdot \mathbf{p}$ so if the solution ψ has \pm helicity, then ψ^{CP} has \mp helicity. The CP conjugation thus converts the particle into the antiparticle. The KP operator also anticommutes with the physical momentum operator so for a state $\psi_1(\mathbf{q})$ with definite helicity \pm and physical momentum \mathbf{q} one has

$$KP\psi_1(\mathbf{q}) = \psi_2(-\mathbf{q}) \quad (16)$$

Instead of the two states ψ_+ and ψ_- , one may consider the superpositions

$$\psi_1(\mathbf{q}) = 2^{-1}[\psi_-(\mathbf{q}) + \psi_+(\mathbf{q})] \quad (17a)$$

$$\psi_2(\mathbf{q}) = 2^{-1}[\psi_-(\mathbf{q}) - \psi_+(\mathbf{q})] \quad (17b)$$

The reason for introducing them is the property

$$KP\psi_1(\mathbf{q}) = \psi_1(-\mathbf{q}) \quad (18a)$$

$$KP\psi_2(\mathbf{q}) = -\psi_2(-\mathbf{q}) \quad (18b)$$

Thus the KP operation applied to ψ_1 or ψ_2 reproduces the state, only traveling in the opposite direction and with a change of phase for ψ_2 . The states ψ_1 and ψ_2 in this way are their own antiparticles. These self-antiparticle states are plane polarized in perpendicular directions. For

the states with momenta in the positive z direction, as given by Eq. (11) and (12), the fields are seen to be

$$E_{1x} = \cos[p\hbar^{-1}(z - ct)] \quad (19a)$$

$$B_{1y} = \cos[p\hbar^{-1}(z - ct)] \quad (19b)$$

$$E_{2y} = \sin[p\hbar^{-1}(z - ct)] \quad (19c)$$

$$B_{2x} = -\sin[p\hbar^{-1}(z - ct)] \quad (19d)$$

with all other components zero.

The final point to be demonstrated here is that only the self-antiparticle type of photon is emitted or absorbed when a system makes a transition between states of definite parity. Consider for simplicity a spinless charged particle described by a Schrödinger wave function $\psi_m(\mathbf{x}, t)$. [The subscripts m and γ are used for the material particle and the photon.] Suppose the particle is bound in some system and makes a transition from an initial state i to a final state f , both eigenstates of parity P , with emission or absorption of a photon. As is well known the transition probability is determined by the interaction integral

$$I = -(e/Mc) \int d^3x [\psi_{mf}^*(\mathbf{x}, t) \mathbf{p} \psi_{mi}(\mathbf{x}, t)] \cdot \mathbf{A}(\mathbf{x}, t) \quad (20)$$

where e and M are the charge and mass of the particle and \mathbf{A} is the vector potential of the photon in the Coulomb gauge,

$$\nabla \cdot \mathbf{A} = 0 \quad (21)$$

Here and below, the integrals extend $\overline{\mathbf{r}}$ over all space. The fields are found from the potential by the relations

$$\mathbf{E} = -c^{-1} \partial \mathbf{A} / \partial t \quad (22)$$

$$\mathbf{B} = \nabla \times \mathbf{A} \quad (23)$$

To make the argument, one first expresses the interaction explicitly in terms of the fields. The potential is found from the fields by integrating this way:

$$\mathbf{A}(\mathbf{x}, t) = \frac{1}{4\pi} \nabla \times \int d^3y \frac{\mathbf{B}(\mathbf{y}, t)}{|\mathbf{x} - \mathbf{y}|} \quad (24)$$

It is easily verified that this expression for \mathbf{A} satisfies Eqs. (21), (22), and (23) by using Eqs. (1), (3), and the fact that $\nabla^2 |\mathbf{x} - \mathbf{y}|^{-1} = -4\pi \delta(\mathbf{x} - \mathbf{y})$. Also it is assumed that fields of interest will be zero outside a finite region of space so that in making partial integrations there are no contributions from infinity. Then by using Eq. (24) and replacing \mathbf{B} by $(\psi_\gamma - \psi_\gamma^*)/2i$, one can rewrite the interaction integral as

$$I = \frac{ie}{8\pi Mc} \int d^3x [\psi_{mf}^*(\mathbf{x}, t) \mathbf{p} \psi_{mi}(\mathbf{x}, t)] \cdot \nabla \times \int \frac{d^3y}{|\mathbf{x} - \mathbf{y}|} [\psi_\gamma(\mathbf{y}, t) - \psi_\gamma^*(\mathbf{y}, t)]$$

However, if i and f are eigenstates of parity, then,

by changing integration variables from \mathbf{x} and \mathbf{y} to \mathbf{x} and $-\mathbf{y}$ in the ψ_i^* term, one sees that

$$I = \frac{ie}{8\pi Mc} \int d^3x [\psi_m^*(\mathbf{x}, t) \mathbf{p} \psi_m(\mathbf{x}, t)] \\ \cdot \nabla \times \int \frac{d^3y}{|\mathbf{x} - \mathbf{y}|} (1 + KP) \psi_i(\mathbf{y}, t)$$

where the factor is $(1 - KP)$ if i and f have the same parity, $(1 + KP)$ if i and f have opposite parity. Since

$$KP(1 \mp KP) \psi_i = \mp (1 \mp KP) \psi_i,$$

only the type of photon that is its own antiparticle can be involved in the transition in either case.

PHOTOSYNTHESIS*

Photosynthesis is briefly summarized and slightly oversimplified by the general equation

where H_2A represents a hydrogen donor and (CH_2O) represents carbohydrate. In green plants, H_2A is water and A is oxygen; in photosynthetic bacteria, H_2A may be any number of reducing substances (e.g., H_2S and ethanol) but is *never* water. The ability of all photosynthetic organisms (both plants and bacteria) to reduce CO_2 to carbohydrate is derived from the ability to utilize the energy of an absorbed photon in a photochemical reaction which produces a powerful reductant X_1 (see Fig. 1) capable of driving the enzymic reactions involved in CO_2 fixation. The ability of green plants (including algae) to evolve oxygen from water is derived from their ability to carry out a second photochemical reaction which produces an oxidant Y_2 (see Figure) capable of

oxidizing water to oxygen. Photosynthetic bacteria lack this second photochemical system.

The primary action of light in photosynthesis is the excitation of pigment molecules. The energy of the photon is first converted to electronic excitation energy, and subsequently stored as chemical energy. Since the number of pigment molecules in general far outnumber the number of primary reactant molecules, the efficient conversion of electronic excitation energy to chemical energy requires efficient transfer of excitation from the site of photon absorption to the site of primary photochemical action. The process generally favored in accounting for this efficient energy transfer is weak resonance interaction, and the array of pigment molecules which feed excitation energy to a single reaction center is known as a photosynthetic unit. Resonance transfer is a nonradiative process which depends upon the overlap of the fluorescence emission spectrum of the donor molecule and the absorption spectrum of the acceptor molecule as well as the separation distance. In the photosynthetic unit, singlet-state excitation resulting from photon absorption migrates from molecule to molecule until trapped by localization in a molecule whose lowest singlet state is below the lowest singlet state of any of its nearest neighbors. This is the reaction center. At the reaction center are the primary reactant molecules which are involved in the primary photochemical oxidation-reduction reaction, the nature of which still remains a matter of lively experiment and debate.

The pigments universally associated with photosynthesis are the chlorophylls. Chlorophyll *a* appears to be essential for oxygen-evolving photosynthesis, and its close relative, bacteriochlorophyll, seems to be required for all bacterial photosyntheses. Other types of chlorophyll as well as nonchlorophyllous pigments have been shown to function as accessory pigments which absorb light and transfer excitation energy to chlorophyll *a* or bacteriochlorophyll. As an example of how the various pigments function, the case of the green photosynthetic bacteria will be cited.⁶ The predominant pigment which serves as the major light absorber in green bacteria is chlorobium chlorophyll with broad absorption bands at wavelengths of 440 and 750 nanometers (nm). A lesser component is bacteriochlorophyll with bands at 371 nm, 603 nm and 809 nm. The reaction center, present in very low concentration, has a band at 840 nm. A quantum of blue light ($\lambda = 440 \text{ nm}$, $E = 2.8 \text{ eV}$) absorbed by one of 200 chlorobium chlorophyll molecules is immediately dropped in energy to 1.7 eV corresponding to the lowest excited singlet state. This excitation energy may be transferred several times between adjacent chlorobium chlorophyll molecules until eventually the transfer to bacteriochlorophyll at 1.5 eV confines the excitation to an array of approximately 20 molecules of which one is the reaction center of energy 1.4 eV. The trapped excitation energy is then converted to chemical energy ($\sim 1 \text{ eV}$) and heat.

In both algae and photosynthetic bacteria,

* Support by the U.S. Atomic Energy Commission is acknowledged.

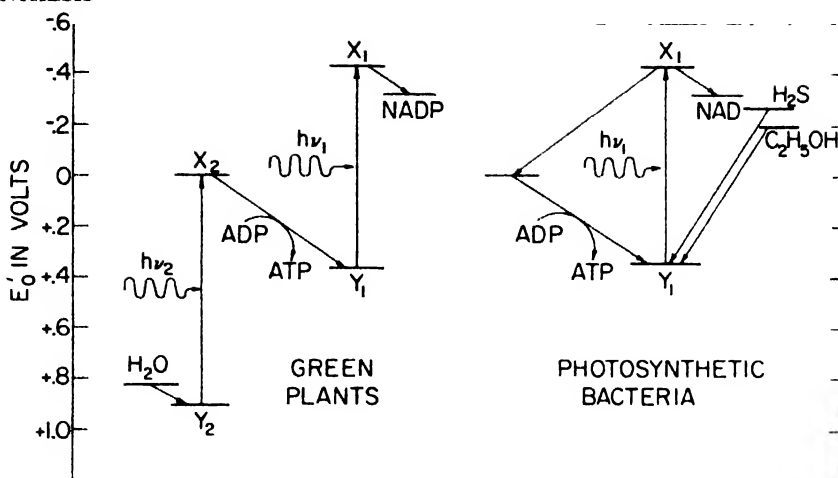

FIG. 1.

most of the measured quantum requirements for photosynthesis have been in the range of 9 to 12 quanta per CO_2 . In algae, the theoretical requirement based on two photochemical reactions in series is 8 quanta per CO_2 or 2 quanta per reducing equivalent. At first glance it would seem that the quantum requirement for bacterial photosynthesis should be half of that for oxygen-evolving photosynthesis, since the bacterial photosynthesis requires only one photochemical reaction. The experimental evidence, however, favors the view that the quantum requirement is about the same in each case. One possible explanation is outlined in the Figure in which the straight arrows denote the transfer of electrons (or equivalent hydrogen atoms) in oxidation-reduction reactions. The curved arrows represent the storage of chemical energy in phosphorylation reactions coupled to electron transfer.

This explanation is based on the well-documented and generally accepted concept that CO_2 reduction in photosynthesis results from a series of enzymic reactions which require reducing power in the form of reduced nicotinamide-adenine dinucleotide (NADH_2) or its phosphate (NADPH_2) and additional chemical energy in the form of adenosine triphosphate (ATP). The photochemical reactions of photosynthesis need only produce sufficient NADH_2 (or NADPH_2) and ATP to drive the following over-all reaction:

According to the hypothesis shown in Fig. 1, the light-driven production of ATP in bacteria competes with the production of reducing power, whereas in oxygen-evolving photosynthesis, ATP production is coupled to the exergonic reactions which link the reductant X_2 , produced by photochemical reaction 2, to the oxidant Y_1 , produced by photochemical reaction 1.

PHOTOVOLTAIC EFFECT

The photovoltaic effect (PVE) is the generation of an emf as a result of the absorption of light. Three phenomena are involved in the effect. The first of these is photoionization, i.e., the generation of equal numbers of positive and negative charges by light absorption. The second is the migration of one or both of the photo-liberated charges to a region where separation of the positive and negative charges can occur.

The third is the presence of a charge-separation mechanism. The photovoltaic effect can occur in gases, liquids and solids, but it has been studied most intensively in solids and, therefore, this discussion will be limited to solids, especially semiconductors.

Photoionization. Semiconductors and insulators are characterized by a threshold energy for photoionization, which is identical with the forbidden energy gap of the material E_g . Thus, photoionization can occur only if the light contains photons whose energy exceeds E_g . Values of E_g range from several electron volts (which would require ultraviolet photons for ionization) to small fractions of an electron volt (infrared photons could cause ionization). Photoionization in metals can also lead to a photovoltaic effect. In this case, the photoionization occurs near the surface and the photo-liberated carriers escape over the barrier at the metal surface (whose magnitude in electron volts will be denoted by W) and enter an abutting semiconductor or insulator, or alternatively, the electrons can be emitted into a vacuum surrounding the metal.

Now the absorption of light in any substance follows Lambert's law which states that

$$N(x) = N(0) e^{-\alpha x}$$

where $N(0)$ and $N(x)$ are the numbers of photons per unit area at a reference point (0) and at a distance x along the direction of propagation of the light beam and α is the absorption constant. Figure 1 shows how α changes with photon energy in a number of semiconductors used in photovoltaic cells. This dependence of α on photon energy (i.e., the color of the light) is of course intimately related to the dependence of the photovoltaic effect on photon energy.

Migration of the Photo-liberated Charges. Because of Lambert's law, the photo-liberated

charges are distributed along the path of the light beam. Normally, they would move about at random until they recombine with carriers of opposite sign. This recombination process is characterized by a mean free lifetime of a pair, which must be large enough to permit the carriers to move to a charge-separation region since the magnitude of the photovoltaic effect depends on the number of charges which move to the charge separation region. The photo-liberated carriers move either by diffusion or under the action of a built-in electrostatic field.

Charge-separation Mechanism. Charge separation requires a change in electrostatic potential between two regions of the solid, so that when a pair of opposite charges migrate to the region of the potential change, one of them can lower its potential by moving across this region. A large photovoltaic effect requires that the change in potential should be large and that it should occur over a distance which is short compared to the mean distance a free carrier can travel before recombination. These requirements imply the presence of a dipole layer which, in turn, implies an abrupt change in some property of the material. Such a dipole layer can occur either at the surface or in the interior of the material. A surface barrier usually involves a metal-semiconductor contact, a contact between the semiconductor and its oxide or, more generally, a contact with some other semiconductor. A barrier inside a material implies an abrupt change in the conductivity, which in the extreme case involves a change of conductivity type, as in a $p-n$ junction.

Photovoltaic Effect at $p-n$ Junctions. The remainder of this article is devoted to the specific case of the photovoltaic effect at a $p-n$ junction. A $p-n$ junction is formed by arranging the chemical impurity distribution in a single crystal of a semiconductor so that electric current is carried primarily by electrons on one side of the junction (the n -side) and primarily by holes on the other side (the p -side). The resulting electrostatic potential profile is such that excess holes can lower their energy by moving from the n - to the p -side while excess electrons lower their energy by moving in the opposite direction. Light absorption in either region leads to an increase in the concentrations of both holes and electrons, but the $p-n$ junction limits the flow of carriers of a given sign to a single direction, and therefore, separates the electrons and holes. If a resistive load is connected between the p - and n -regions, the current through the load I_L is represented adequately by the equation

$$I_L = I_s - I_0(e^{\Delta V} - 1)$$

where I_0 and Δ are functions of the absolute temperature, material parameters and the fundamental constants; I_s is the photo-generated current which would flow if the junction were short circuited. The parameter I_s is a function of the absorption constant α , the carrier lifetime τ , the spectral composition of the light and the geometry of the junction.

Applications. The photovoltaic effect can be

FIG. 1.

used to convert light to electricity and, indeed, p - n junction photovoltaic cells in silicon have been the principal power sources on space satellites. The effect can of course be used to detect small amounts of radiation, and its sensitivity compares favorably with that of photoconductive detectors. The ionizing radiation need not be light so that this effect can also be used to detect x-rays, fast electrons, protons, etc. Studies of the spectral response of the photovoltaic effect can yield valuable information about basic material parameters like α , τ , E_g , σ , etc. The photovoltaic effect provides a convenient tool for studying radiation damage in semiconductors. It is also a basic phenomenon in phototransistors.

PHYSICAL ACOUSTICS

Sound waves in the ideal sense are mechanical disturbances propagating in a continuous medium. The basic fact of interest from a physical standpoint is that these waves carry momentum and energy without a net transport of mass. However, there are two other facts worth mentioning which are that sound waves propagate in almost all substances and that sound waves can be used to study the physical properties of, or to cause physical changes in the substances through which they propagate.

In practice, the approximation that natural materials are continuous fails when the wavelength is short enough to be comparable to interatomic or intermolecular distances--in a gas, the mean-free-path of a molecule; in a solid, the distance between atoms. The region of validity of the approximation that the waves are of small amplitude is more difficult to circumscribe since it depends on more than one property of the medium. In most cases, the approximation is valid when the disturbance in the velocity of the medium as the wave passes is small compared to the speed of sound in the medium. In air under normal conditions, this will occur when the pressure disturbance becomes an appreciable fraction of atmospheric pressure. In liquids and solids, however, pressure disturbances of hundreds or thousands of atmospheres propagate as small-amplitude waves. The low compressibility, or high "stiffness," of these media increase the speed of sound and at the same time require a larger pressure fluctuation to produce a given velocity fluctuation. If the medium is in a critical

state, however, the definition of what constitutes a small disturbance can depend on other factors. For example, cavitation in a liquid occurs at particular sites that are called cavitation nuclei. While the reasons for the existence of these sites in a fluid are not completely understood, it is clear that they are regions that are subject to fracture at pressures far below those that would fracture the pure liquid.

The energy transported by the wave per unit area normal to the direction of propagation is called the intensity and can be measured in watts per square meter (the mixed unit, watt per square centimeter, is also in common use). A sound wave in air of intensity comparable to that of sunlight would be just beyond the pain threshold of the ear, so the energy of sound waves is not normally felt. The principle of conservation of energy applied to the energy transported by the waves, however, is a powerful investigational tool. The momentum transport per second per unit area is the intensity divided by the wave speed. Since this is also true for electromagnetic waves, it follows that a sound wave in air (speed 330 m/sec) of a given intensity transports about a million times more momentum than an electromagnetic wave of the same intensity. When the wave is absorbed or reflected, there is a radiation pressure on the absorber or reflector equal to the rate of change of momentum per unit area that is I/c on a perfect absorber and $2I/c$ on a perfect reflector, where I is the intensity and c the speed of sound. The measurement of this pressure is a fundamental method for measuring the amplitude of the wave.

The basic equations for a continuous medium are the continuity equation, which is an expression of the law of conservation of mass, and the Navier-Stokes equation, which relates the time rate of change of momentum in each volume element to the forces on the element. An additional equation is required that relates the scalar pressure forces to the other variables. While this third equation must be derived from the laws of thermodynamics, a relationship that is widely applicable is

$$\rho = \kappa \rho_0 p$$

where κ is the compressibility of the medium, ρ_0 is the ambient density, and p and ρ are the disturbances in pressure and density associated with the wave. This relationship is useful as long as the wave does not change the value of κ appreciably. If there is no dissipation in the medium or if the dissipation is viscous, p and ρ will be in phase. In cases where dissipation exists due to irreversible heat flow, or the stress-strain relationship contains time derivatives, the equation can be retained by allowing κ to become complex. There are then three equations in three dependent variables which are p , ρ and the velocity disturbance u .

The equations have a unique solution only if certain boundary conditions are applied. In the case of an unbounded medium, the boundary condition is that all sources of sound must

radiate energy outward, and this is sufficient to produce a unique solution. In a bounded region, reflections must be taken into account. A sufficient boundary condition is that the impedance of the boundary, defined as the ratio of the pressure disturbance to the normal component of the velocity disturbance, be specified at each point on the boundary. In simple cases, the boundary conditions can be satisfied by a superposition of elementary solutions. The impedance tube is an example of a case where plane waves are used to measure the reflective and absorptive properties of a sample placed at one end of the tube in terms of the incident and reflected waves. The details of the distribution of sound in an auditorium, however, can be a complex problem. Another approach is to reformulate the equations as an integral equation containing the boundary conditions explicitly. This integral equation, a mathematical expression of Huygens' principle, is known in acoustics as Kirchhoff's formula. A third approach is to include the boundary conditions in the differential equations. An example of this procedure is the propagation of sound in a duct of varying cross section. If the change in width of the duct per wavelength is small compared to the wavelength of sound in the duct, the shape of the duct can be introduced into the continuity equation. This procedure leads to the "horn equation" which describes sound propagation in flared ducts. The subject of boundary conditions is further complicated by the fact that waves may propagate in the boundary itself. A boundary characterized by the fact that each point behaves independently is called a locally reacting boundary. If neighboring parts of a boundary interact to support wave motion, the boundary is non-locally interacting, and if the wave speed in such a boundary is higher than in the medium, energy can propagate along the boundary and leak back into the medium. In such a case, the wave may find a shorter time travel path through the boundary than through the medium itself.

Sound waves are generated in regions where time-varying forces act on the medium. While in some cases it may be convenient to think in terms of boundary conditions, this is not always convenient or even possible. A moving piston, such as the cone of a loudspeaker, can be thought of as a boundary condition in that the normal velocity, or pressure gradient, is specified. Sound generated by a region of turbulence, however, cannot be treated in this fashion because the source strength is distributed over the entire turbulent volume and not restricted to a surface. In fact, in the region of turbulence it is difficult to separate the motion of the medium into hydrodynamic and acoustical components. If the mechanism of sound generation is confined to a definite region, it is natural to describe the sound field at a distance in terms of spherical harmonics, and the amplitudes of these harmonics can be related to integrals of moments of the motion of the medium taken over the source region. The most simple natural source, the

monopole, can be described as a periodic injection and removal of mass at some point in the medium. In a stationary medium, the wave fronts are concentric spheres and the pressure disturbance is proportional to the time rate of change of mass flow. The next higher spherical harmonic, the dipole, is related to the net fluctuating force on the medium. For example, if an airfoil is subject to fluctuating lift and drag forces, there are equal and opposite forces exerted on the medium. These forces give rise to dipole sound radiation, and the sound pressure is proportional to the time rate of change of the forces. The sound fields generated by turbulence and by earthquakes are related to the integral of shear motions over the source volume and have a quadrupole distribution.

If the ambient properties of the medium are everywhere the same, the medium is said to be homogeneous. A uniform translational motion of the medium, however, deserves special attention. While a suitable coordinate transformation can remove a translational motion without changing the basic equations, such a transformation does not remove relative motion between the medium and any sources or receivers, and such motion causes the medium to be anisotropic. Although a receiver is never completely passive, the usual approximation is to assume that it is. In this case, the receiver has no physical effect on the medium and simply registers what it sees. A source, on the other hand, is contributing energy and momentum to the medium, and the distribution of these quantities is affected by the motion. Surfaces of constant phase are carried along by the medium in the same way as ripples from a pebble dropped in moving water, and for a monopole source at rest in a moving medium, they form spheres centered a distance RU/c downstream from the source, where R is the radius of the sphere, U the speed of the medium, and c the speed of sound in the medium at rest. The surfaces of constant pressure for such a source, on the other hand, are ellipsoids of revolution centered at the source with the minor axis in the flow direction. It follows that the intensity is greater to one side than it is at an equal distance either upstream or downstream. In general, the problem is complicated by the fact that the energy flow vector is not perpendicular to a surface of constant phase.

The dispersion relationship for acoustic plane waves relates the phase velocity and attenuation (or growth) of these waves to physical properties of the medium.

Classically, the important parameters for a fluid are viscosity and heat conduction. While a general solution including these parameters leads to a sixth-order polynomial, in cases where they are small the problem can be solved to a good approximation by three pairs of roots representing two plane waves, two viscous shear waves, and two thermal waves. The plane waves, traveling to the left and right, are attenuated slightly by viscosity and heat conduction. The shear waves and thermal waves are not excited in the

bulk of the medium. At boundaries, the shear and thermal waves will exist, however, to satisfy tangential velocity and thermal boundary conditions. While the viscous and thermal waves exist only in thin boundary layers (the real and imaginary parts of the propagation constant are equal), they may be responsible for a major part of the absorption. For example, in the case of plane waves propagating in air in a pipe the ratio of boundary absorption coefficient to bulk absorption coefficient is about $10^8/Lf^{3/2}$ where L is the ratio of the area of the pipe to its perimeter and f is the frequency. For very narrow pipes, the ratio is larger.

In general, the measured value of attenuation of plane waves exceeds the classical predictions based on heat conductivity and viscosity. The discrepancy varies not only from one substance to another but also may depend on the past history of the substance. The additional attenuation is caused by (and reflects) interactions between particles on a small scale compared to a wavelength—in other words, between individual atoms, molecules, or groups of molecules. The problems are as various as the chemical properties of matter.

In solids, it has been shown that dissipation usually is related to departures from ideal crystalline structure on a relatively large scale. Annealing greatly reduces the attenuation of sound. In fluids, it has been shown, however, that attenuation can be related to interatomic binding forces as well as the forces binding clusters of molecules. The vibrational relaxation of O_2 in air and of magnesium salts in water, for example, can account for the excess attenuation of sound waves in the atmosphere and in seawater.

PHYSICAL CHEMISTRY

Physical chemistry emerged as a separate discipline in the second half of the nineteenth century, van't Hoff, Ostwald and Arrhenius contributed conspicuously in laying its foundation; van't Hoff is especially remembered for

his explanation of osmotic pressure. According to him, a solute in a vessel separated from pure solvent by a membrane permeable only to the solvent exerts the same pressure which the same number of moles of gas would if confined in the same volume. In exerting this pressure, the solute draws solvent through the semipermeable membrane except as it is restrained by a pressure equal to the osmotic pressure. He also codified equilibrium theory in his celebrated "Études de Dynamique Chimique" published in 1884. It is interesting that van't Hoff received the first Nobel prize for chemistry in 1901.

Ostwald's dilution law and Arrhenius' theories of reaction rates and of the ionization of electrolytic solutions played key roles in getting physical chemistry off to an impressive beginning. Willard Gibbs' development of thermodynamics and statistical mechanics and van der Waals' equation of state are further milestones in the onward march of the new discipline.

Physical chemistry is the attempt to codify into laws the many qualitative observations made on all types of molecular systems. Such an ambitious goal can only be achieved by using the full spectrum of experimental and theoretical procedures. Atoms are known to consist of positive nuclei surrounded by electrons circulating in orbits about the nuclei. Since the electrostatic and magnetic laws of force are known for the atoms and since with wave mechanics we can express the laws of motion of particles in terms of the known potentials, it follows that the laws of chemistry are known. As a consequence of this, all properties of atoms and molecules can be calculated exactly, in principle. Nevertheless, such calculations are so difficult that only for the simplest systems can the calculations be carried out exactly. However, even for complicated systems, wave mechanics provides the framework into which all observations can be fitted.

Bohr's Model of the Atom. It seems useful to trace quantum mechanics briefly from its beginnings. In 1913, Bohr working in Rutherford's laboratory, postulated that the angular momentum, $mr^2\omega$, of an electron moving in a circle about a nucleus, when multiplied by the number of radians, 2π , in the circular orbit, must equal some integer n times Planck's unit of action h . Accordingly he wrote

$$mr^2\omega 2\pi = nh \quad (1)$$

He also equated the centrifugal force, $mr\omega^2$, to the coulomb force of attraction, e^2/r , to give

$$mr\omega^2 = \frac{e^2}{r^2} \quad (2)$$

Finally the total energy E is the sum of the kinetic energy $\frac{1}{2}mr^2\omega^2$ and the potential energy $-e^2/r$, that is

$$E = \frac{1}{2}mr^2\omega^2 - \frac{e^2}{r} = -\frac{1}{2}\frac{e^2}{r} \quad (3)$$

Here, m , r and ω are the reduced mass of the electron, the radius of the electron orbit, and the angular momentum, respectively. Solving these equations we find for the radius

$$r = \frac{n^2 h^2}{4\pi^2 m e^2} \quad (4)$$

and for the energy

$$E = - \frac{2\pi^2 m e^4}{n^2 h^2} \quad (5)$$

The number n is the principle quantum number. Equation (5) may be used to predict the spectra of hydrogen exactly, and thus constituted a great step forward in explaining atomic structure. The energy for a single electron circulating about a nucleus of charge ze is

$$E = - \frac{2\pi^2 m z^2 e^4}{n^2 h^2} \quad (6)$$

If an electron is circulating about a nucleus whose charge is ze , but whose effective charge is reduced to $(z-s)e$ by a screening cloud of other electrons, there is a corresponding reduction of the electron's binding energy to

$$E = - \frac{2\pi^2 m e^4 (z-s)^2}{n^2 h^2} \quad (7)$$

Here, s is called the screening constant. Equation (7) explains much of chemistry. In spite of this agreement, Bohr's theory is incomplete since it provides no procedure for calculating the screening constant.

The De Broglie Wavelength. In the middle twenties, this complication was resolved by the advent of quantum mechanics. The matrix theory of Heisenberg was followed by De Broglie's interpretation of particle motion as wave motion. In the new theory, Bohr's quantization of orbits as formulated in Eq. (1) was replaced by the idea that the circumference of a circular orbit, $2\pi r$, must be an integral number of wavelengths, $n\lambda$. Thus,

$$n\lambda = 2\pi r = \frac{n^2 h^2}{2\pi m e^2} \quad (8)$$

Substituting into Eq. (8) the value for the momentum, p , obtained from the kinetic energy equation $p^2/2m = \frac{1}{2}e^2/r$ leads to the famous De Broglie relation

$$\lambda = h/p \quad (9)$$

This same result applies to photons, which have both a particle and a wave aspect. Thus, according to Einstein

$$E = h\nu = mc^2 = mc\lambda\nu \quad (10)$$

Whence

$$\lambda = \frac{h}{mc} = h/p \quad (11)$$

Confirmation of the De Broglie wavelength for electrons was soon provided by Davisson and Germer and by G. P. Thomson who demonstrated that electrons were in fact diffracted by crystalline materials much as x-rays are.

The Wave Equation. Schrödinger took the next step by substituting into the wave equation

$$\frac{1}{a^2} \frac{\partial^2 \psi}{\partial t^2} = \frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} + \frac{\partial^2 \psi}{\partial z^2} \quad (12)$$

values for a , the wave velocity. Thus

$$a = \lambda\nu = \frac{hE}{p} = \frac{E}{\sqrt{2m(E-V)}} \quad (13)$$

Here ψ is the amplitude of the wave, while t is the time and x , y and z are the coordinates of position for the particle. For stationary waves, the amplitude may be expressed as

$$\psi = \phi(x, y, z) e^{-\frac{2\pi i Et}{h}} \quad (14)$$

which when substituted along with Eq. (13) into Eq. (12) leads to Schrödinger's famous time-independent equation

$$\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} + \frac{\partial^2 \phi}{\partial z^2} + \frac{8\pi^2 m}{h^2} (E - V) \phi = 0 \quad (15)$$

From Eq. (14), we note that

$$-\frac{h}{2\pi i} \frac{\partial}{\partial t} \psi = E\psi \quad (16)$$

Using this result we see that Eq. (15) may be generalized to the time dependent form

$$\left[-\frac{h^2}{8\pi^2 m} \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \right) + V \right] \psi = -\frac{h}{2\pi i} \frac{\partial \psi}{\partial t} \quad (17)$$

Now since ϕ in Eq. (15) is the amplitude of the wave, the square of the amplitude $|\phi|^2$ is necessarily interpreted as proportional to the probability of a particle being at a point in space, just as the square of the amplitude of the wave expresses the density of radiation at a point in physical optics. Restricting the allowed solutions of Eq. (15) to those eigenfunctions ϕ which have acceptable values leads to the allowed values of the energy E which Bohr found for hydrogen.

It is important to note that we now have a theory that can be generalized to many particles. The operator in square brackets on the left of Eq. (17) is just the expression for the energy of a particle providing $h/2\pi i \partial/\partial x$, $h/2\pi i \partial/\partial y$ and $h/2\pi i \partial/\partial z$ are replaced by the corresponding momenta p_x , p_y and p_z respectively. Analogously $-h/2\pi i \partial/\partial t$ is the operator for the energy E or H as was noted in arriving at Schrödinger's time-dependent equation. It thus seems natural to generalize Eq. (17) to many particles by having V express the total potential energy for the system

and taking as the operator for the kinetic energy, the sum over all particles

$$\sum_i \left[-\frac{h^2}{8\pi^2m} \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \right) \right]$$

This is not the place to elaborate quantum mechanics in detail, but clearly it completely transforms physical chemistry from an almost exclusively experimental discipline to one for which there is a fundamental theory as well.

Mean Values of Properties. According to quantum mechanics, the mean value of any property, x , of a system in the state ψ_i having the energy ϵ_i is

$$\bar{x}_i = \int \psi_i^* x \psi_i dT$$

Here x is the quantum mechanical operator for the property x , it is obtained from the latter by replacing each momentum p_i by $h/2\pi i \partial/\partial q_i$, where q_i is the corresponding positional coordinate, and keeping the q 's and t unchanged. If there are ambiguities, x must be chosen to give real values for the calculated property. Now since the probability, p_i , of a system at equilibrium being in the state ψ_i is

$$p_i = \frac{e^{-\epsilon_i/kT}}{\sum_i e^{-\epsilon_i/kT}} \quad (18)$$

the mean value of the property, x , for the system is

$$\langle x \rangle = \frac{\sum_i \bar{x}_i e^{\epsilon_i/kT}}{\sum_i e^{-\epsilon_i/kT}} \quad (19)$$

Thus, in principle, the values of all properties can be calculated. Actually such calculations are quite difficult and are rarely carried through exactly. The sum $\sum_i e^{-\epsilon_i/kT}$ over all the states is called a partition function and is frequently represented by the symbol f .

Statistical Mechanics. Statistical mechanics whose beginnings go back to Maxwell and Boltzmann was greatly developed and systematized by J. Willard Gibbs. It provides still another cornerstone of theoretical physical chemistry.

The probability, P_i , of a system being in the state i with energy ϵ_i is already given in Eq. (18). The average energy E is accordingly

$$E = \frac{\sum_i \epsilon_i e^{-\epsilon_i/kT}}{\sum_i e^{-\epsilon_i/kT}} \equiv kT^2 \frac{d \ln}{dT} \left(\sum_i e^{-\epsilon_i/kT} \right) \quad (20)$$

But, from thermodynamics, we have for the average energy of a system

$$E = -T^2 \frac{\partial(A/T)}{\partial T} \quad (21)$$

Here, A is the Helmholtz free energy and $A_1 - A_2$ is the maximum work a system can be made to perform at constant temperature in passing from

state 1 to state 2. Equating the two values of E , given in Eqs. (20) and (21) and integrating gives

$$A = kT \ln \sum_i e^{-\epsilon_i/kT} + cT \quad (22)$$

Here c is an integration constant. Now the lowest state of the system must be nondegenerate and c must be zero in order that Eq. (22) will yield zero entropy for the system at the absolute zero of temperature as is required by the third law of thermodynamics. Thus, we can write the exciting result

$$A = -kT \ln \sum_i e^{-\epsilon_i/kT} \quad (23)$$

as the fundamental equation relating statistical mechanics and thermodynamics. If the energy levels ϵ_i are known as functions of the volume of the system, then A is known as a function of V and T , and all the thermodynamic properties of the system can be calculated.

Equilibrium Theory. The probability, P_i , of a system which obeys Boltzmann statistics, being in the i th state is equal to n_i/N where n_i is the number of systems in the i th state and N is the total number of systems. Thus we can rewrite Eq. (19) in the form

$$\frac{n_i}{e^{-\epsilon_i/kT}} = \frac{N}{\sum_i e^{-\epsilon_i/kT}} = \lambda = e^{\mu/kT} \quad (24)$$

Here λ is called the absolute activity and μ is the chemical potential. For a system at equilibrium we can write

$$aA + bB + \cdots = dD + eE + \cdots \quad (25)$$

Here, a molecules of substance A reacts with b molecules of B to give d molecules of D plus e molecules of E, etc. According to thermodynamics, a system at equilibrium is incapable of doing work so that the reaction involves no change of chemical potential.

Thus,

$$a\mu_A + b\mu_B + \cdots = d\mu_D + e\mu_E + \cdots \quad (26)$$

and

$$\lambda_A^a \lambda_B^b \cdots = \lambda_D^d \lambda_E^e \cdots \quad (27)$$

Whence

$$\frac{(n_A)^a}{f_A^a} \frac{(n_B)^b}{f_B^b} \cdots = \frac{(n_D)^d}{f_D^d} \frac{(n_E)^e}{f_E^e} \cdots \quad (28)$$

Here n_A is the number of molecules of the A th kind distributed over the partition function f_A with analogous meanings for the other symbols. If we define c_A as the concentration of A then we have

$$n_A/V = c_A \quad (29)$$

and $f_A/V = F_A$. Here F_A is the partition function per unit volume. Equation (29) can now be rewritten in the form of an equilibrium constant K_c . Thus

$$K_c = \frac{(C_D)^d (C_E)^e \cdots}{(C_A)^a (C_B)^b \cdots} = \frac{F_D^d F_E^e \cdots}{F_A^a F_B^b \cdots} \quad (30)$$

Now even when systems do not obey Boltzmann statistics, we still have Eqs. (26) and (27) remaining true with the auxiliary equation

$$\left(\frac{\partial A}{\partial n_A}\right)_{V, T, n_n} = \mu_A \quad (31)$$

as well as the other analogous equations. Thus equilibria for systems obeying all types of statistics are readily formulated using statistical mechanics. We now turn to rates of reaction.

Reaction Rates. A chemical reaction ordinarily proceeds slowly because it involves passage through a transition state, which is difficult to attain. The transition state lies at the saddle point of a landscape separating two valleys, one corresponding to reactants and the other to products. Such landscapes are ordinarily multi-dimensional. The path through the saddle point is called the reaction coordinate. A system at the saddle point is called the activated complex and is like other molecules except for its fleeting passage along the reaction coordinate. The reaction coordinate of the activated complex can be treated as a translational degree of freedom if due account is taken of reflection and barrier leakage. Since the transition state is the point of no return, it is the logical region for calculating the rate of reaction. If we rewrite Eq. (25) to include the activated complex C^\ddagger , we have

The rate of reaction in the forward direction, r_f , at equilibrium is

$$r_f = \mathcal{H} \frac{1}{2} C_{\delta^\ddagger} \bar{u} \cong \mathcal{H} \frac{1}{2} C^\ddagger \frac{(2\pi mkT)^{1/2}}{h} \delta \left(\frac{2kT}{\pi m}\right)^{1/2} \frac{1}{\delta} \\ = \mathcal{H} C^\ddagger \frac{kT}{h} = \mathcal{H} F^\ddagger \frac{kT}{h} \lambda_r^\ddagger \quad (33)$$

here \mathcal{H} is the transmission coefficient which corrects the rate for reflection, barrier leakage and non-equilibrium; \bar{u} , the average velocity across the barrier, has the value $(2kT/\pi m)^{1/2}$; C_{δ^\ddagger} is the concentration of activated complex per length δ along the reaction coordinate while C^\ddagger is the same quantity per single quantum state along the reaction coordinate. F^\ddagger and λ_r^\ddagger are the partition functions per unit volume and the absolute activity of the activated complexes moving in the forward direction, respectively. The net rate is thus

$$r = \mathcal{H} \frac{kT}{h} F^\ddagger (\lambda_r^\ddagger - \lambda_b^\ddagger) \quad (34)$$

Here λ_b^\ddagger is the absolute activity of reactants moving in the backward direction and may be replaced by the product of the absolute activities of the products of reaction while λ_r^\ddagger may be replaced by the products of the absolute activities of the reactants; r is of course zero at equilibrium.

Experimental Methods. In recent times, physical

chemistry has added many new techniques to the standard procedures which were used earlier in such fields as solution chemistry and in gas kinetics. Analysis of the products of reaction by mass spectrography has solved many difficult kinetic problems. Computer techniques have greatly speeded up structure determination by x-rays and by other diffraction techniques using electrons and neutrons. The development of radar in wartime provided a basis for microwave spectroscopy. Microwaves with wave lengths around one centimeter can be used to study the inversion of ammonia and internal rotations around C—C and other bonds. Microwave spectroscopy, because of the extremely long wavelengths involved, brings phenomenal precision into molecular structure measurements.

Nuclear magnetic resonance, measuring as it does the magnetic moments of atomic nuclei, reveals the different diamagnetic and paramagnetic environments surrounding atoms. For example, one can distinguish various environments of hydrogen and rates of migration between such environments. Electron spin resonance yields parallel information about the unpaired electrons. Thus free radicals are detected, and changes involving them are followed.

Chromatography makes use of the differential distribution of the components of a mixture between a stationary and a moving phase separating the components because of the different times that they require to traverse a column. At low temperatures, even *ortho*- and *para*-hydrogen can be separated by helium moving past carbon. Chromatographic separation is in fact one of the milestones in chemistry.

Valence and Molecular Structure. The electron pair bond of G. N. Lewis is explained in terms of quantum mechanics and the Pauli Exclusion Principle. Thus quantum mechanics is used to find the best bonding orbitals and the Exclusion Principle requires that only two electrons having unlike spins can occupy the orbital. The recent discovery of fluorides of the rare gases shows that novel findings are still possible in valence and molecular structure. Pauling has given us an interesting presentation of valence in his book with that title.

Thermodynamics. The thermodynamics of solutions is developing along the lines of providing mechanistic models to explain activity coefficients at the higher concentrations not explained by Debye-Hückel theory. This gives added insight into the structure of solutions. Better models are being developed to explain simple liquids. The best of them yield very realistic calculations of the properties of liquids.

Concluding Remarks. The boundaries between disciplines regularly grow more blurred with time. This is especially true of the border between chemistry and physics. Here physical chemistry or chemical physics continues to spread into new fields with no ends in sight. Physical chemistry's second century should be even more spectacular than the first has been.

PHYSICS

Physics can be defined as the branch of natural science that treats those phenomena of material objects included in the subjects of mechanics, properties of matter, heat, sound, light, electricity and magnetism, and molecular and atomic processes. It describes and correlates energy and radiation, and has sometimes been defined as the study of matter and energy. While such definitions attempt to distinguish between physics and other sciences, it should be stressed that physics is not set off by itself, but is very closely related to other sciences, and there is a good deal of overlap with their spheres of interest. In many cases, the differences are merely matters of emphasis. Chemistry stresses the regrouping of atoms to form new compounds, while physics picks a particular substance and studies its behavior. Biology restricts its interest to living organisms, while physics largely omits them from its consideration. Geology confines its investigations to the earth itself and the inanimate material of which it is composed. Astronomy, on the other hand, finds its field of interest in the vast expanses of space which run on and on away from the earth.

The extent to which these sciences overlap is shown by the special branches of science dealing with borderline areas. Astrophysics treats physical phenomena as they occur in regions beyond the immediate vicinity of the earth. It includes studies of the physical processes in stars and of the nature of the radiations they emit. Physical chemistry, as its name implies, covers phenomena common to both physics and chemistry. Energy relations in chemical reactions and the effects of changes in temperature or pressure on the reactions are samples of the topics included. Geophysics relates physics and geology, and involves studies of the earth's magnetism and the effects of high pressure in the earth's interior. Biophysics deals with the physical processes that are of specific interest to the study of living organisms. Each of these fields has grown to include a vast array of scientific knowledge, and each is discussed in a separate article in this book.

The field of engineering is closely related to physics and other sciences. In general, it can be said that as knowledge about some specific topic grows to the point where use can be made of it in every-day life or in industrial processes, the topic passes over to engineering, and engineers develop and improve things using the basic information. Scientists concern themselves with the basic phenomena themselves, while engineers direct their efforts toward the solution of problems dictated by specific applications.

Historical Background. The word "physics" can be traced to the Greek word *physos*, meaning nature. All studies about nature were grouped together by the Greek philosophers, but in many

cases theories suffered from a lack of experimental research, so that the name, "natural philosophy" was more descriptive of their efforts than a name such as "natural science" would have been.

A summary of the important features in the development of physics from its early beginnings to the present advanced state can be found in the article on HISTORY OF PHYSICS.

Major Divisions of Physics. For purposes of study, physics can be reasonably well divided into major areas, which will be discussed briefly here and in greater detail in other articles in this book.

Mechanics is the science of the motions of material bodies, the forces which produce or change these motions, and the energy relations involved. Newton's three laws of motion and his law of gravitation form the foundation of this study. Work, momentum, vibration, wave motion, pressure, elasticity, and viscosity are other topics considered to be parts of mechanics.

Heat is the energy which an object possesses by virtue of the motions of the molecules of which it is composed plus the potential energy resulting from interatomic forces. The field is of great importance to other areas of learning, as well as to physics, and appears as a topic in chemistry and engineering. The term heat is also used in a different but related sense to indicate energy in the process of transfer between an object and its surroundings because a difference exists between their temperatures. Thermodynamics is the name given to the study of the relationships between heat and mechanics.

Acoustics is the science of sound. Sometimes wave motion is studied under acoustics rather than under mechanics because sound provides good illustrations of wave motion. Objects which are in vibrating motion in a medium can set that medium in motion, and the disturbance can travel through the medium in the form of a wave. Energy is transferred without the transfer of particles of the medium. Sound is the type of wave motion which has such a frequency that, if it reaches a human ear, it can cause a stimulus to reach the brain and hearing results. Thus, to the physicist, sound is the wave motion itself. Sound can also be defined as the sensation produced when sound waves reach the ear. Because both definitions are in common use, care must be taken to avoid confusion.

Light is the particular part of the gamut of electromagnetic waves to which the eye responds. Here, varying electric and magnetic fields travel through a vacuum or a transparent medium. The energy travels in even multiples of specific small amounts called "quanta." Related to light are infrared radiations, those frequencies which are just too low to cause the sensation of light in the normal human eye, and ultraviolet rays, similar radiations whose frequencies are just too high for the human eye. Optics, which is the study of light, often includes infrared and ultraviolet radiation.

Electricity and magnetism are so closely related that neither topic can be studied in any depth without involving the other. Electricity deals with

the forces which charged particles exert upon each other, the effects of such forces, and the phenomena caused by the motions of charged particles. Magnetism was first known in the form of the peculiar attraction which a mineral called lodestone exerted because of the particular electron orientations in the material. It was found that magnetic effects could be caused or altered by electric currents. Further, it is possible to use magnetic materials to advantage in producing electric currents, which are streams of charged particles. An important branch of electricity is electronics, and this area has attracted the attention of more physicists in this country than any other part of physics. This subject deals with the flow of electric currents in vacuum tubes, semiconductors, and associated circuits, and with the use of these circuits to form devices of many kinds.

Solid-state physics is a well established area cutting across some of the other areas mentioned above. It includes those phenomena which are exhibited by materials in the solid state, with emphasis on electronic properties and their relations to the composition of crystalline substances and to energy levels in these materials.

Modern physics is a title under which physicists group many topics of comparatively recent development involving or relating to atoms and other submolecular particles or radiation resulting from atomic processes. Subjects which are considered here include radioactivity (both natural and artificially induced), x-rays, atomic and molecular structure, the quantum theory, wave mechanics and matrix mechanics, and nuclear fission and fusion.

Experimental physics and theoretical physics are two general categories into which the entire field of physics can be divided. The experimentalist attempts to discover new phenomena through the manipulation of apparatus and to make measurements of old or newly discovered properties. The theoretical physicist attempts to correlate measurements and to simplify theories. He tries to predict new phenomena and to relate one effect to another. Mathematical physics uses mathematics to describe physical phenomena, and extends or adapts mathematics to make it applicable to specific theories.

General discussions of major areas of physics can be found in the cross-references listed at the end of this article.

Future Trends. It is of course impossible to predict the flow of any science as it varies from quiet pools to violent rapids. Present trends lead one to expect that certain areas will receive emphasis, but a new discovery or even gradual progress in an old area can open up vast new vistas. Computers and computer techniques are speeding calculations on nuclear forces, and some of the riddles of their existence may yield to intense pressures. Fundamental-particle physics is another region with many questions which have been posed but not answered. Which, if any, of the particles are truly fundamental? And what does "charged" imply when applied to particles?

What will even more powerful accelerators reveal? The emission of coherent radiation and its behavior combine to form an area in which effort is being accelerated. The Fermi surfaces of metals and superconductivity and other cryogenic phenomena are fruitful, lively and interesting areas. Undoubtedly more and more surprises are in store from expanding research programs.

Physics Organizations. Throughout the world there are many societies and other organizations that have the objectives of advancing physics and distributing knowledge of that science. In addition, other organizations deal with broader or related fields and include physics as part of their interests. In the United States of America, five societies—the Acoustical Society of America, the American Association of Physics Teachers, the American Physical Society, the Optical Society of America, and the Society of Rheology—are members of the American Institute of Physics, which was set up to assist them in their activities. Many other organizations are associated or affiliated with the Institute. It maintains an Information Center on International Physics Activities and publishes an "Information Booklet on Physics Organizations Abroad." Inquiries should be sent to the director of the Information Center, American Institute of Physics, 335 East 45th Street, New York, N.Y. 10017, U.S.A. In addition, scientific personnel attached to embassies in Washington, D.C. can provide information about activities in their respective countries.

PLANCK'S LAW. See **RADIATION, THERMAL.**

PLANETARY ATMOSPHERES

The atmospheres of the planets within our solar system are very different from each other; in fact, no two planets have identical atmospheres. Nevertheless, the planets can be divided into two major categories within which some similar characteristics are present. These two categories are the "terrestrial" planets, earth, Venus, Mars Mercury, which are fairly high-density solid planets with relatively thin atmospheres, and the "giant" planets, Jupiter, Saturn, Uranus, and Neptune, which have much lower densities and extensive atmospheres.

Within these categories, a distinction can be made between those characteristics such as temperature and concentration of impinging radiant energy, which are determined primarily by the planet's distance from the sun, and others, such as

escape velocity, which are determined by the mass of the planet itself. However, these distinctions are subject to variation, due to interaction of various environmental factors, and as a result, each planet must be considered individually for best understanding.

Our own planet, naturally, is the one about which we have the most extensive information and thus is the one which is best understood. Conclusions about the nature of other planetary atmospheres must often be made from very inadequate data and consequently may sometimes be speculative. Our major sources of information about the composition of other planetary atmospheres are the spectroscopic studies made by astronomers for many years. Tables 1 and 2 list important data for the various planets.

Terrestrial Planets. *Mercury* is the closest planet to the sun and, as expected, has the highest surface temperature. With its low mass, Mercury has a correspondingly low escape velocity and any atmosphere present in the past should have escaped to space. Since its period of rotation is equal to its period of revolution, Mercury always turns the same face toward the sun. The dark side, therefore, is very near absolute zero. Urey¹ has discussed the possibility that a very thin atmosphere of high-molecular-weight substances may exist and account for the transient haze sometimes observed on the planet.

The atmosphere of *Venus* is somewhat mysterious at present despite centuries of observation. The only major constituent which has been positively identified is CO₂, which is known from spectroscopic measurements to be present to the extent of 10⁵ cm-atm above the cloud layer. From cosmic abundance data nitrogen is also expected as a major constituent. Hydrogen and helium would have escaped to space over geologic ages. Trace amounts of CO and O₂ should be present from photodissociation of CO₂ in the upper atmosphere, and these gases have recently been observed spectroscopically in very low abundance. In the upper atmosphere, O₂ will be dissociated

into O atoms, and the CO and O atoms can recombine to regenerate CO₂ in a number of ways, for example:

Thus the dissociation products do not accumulate to any large extent. Water vapor has not been observed with certainty, although reports have been published of the possible presence of trace amounts. It seems unlikely that either atmospheric or surface water can be present in significant amounts for two reasons. The first is the high level of CO₂ in the Venus atmosphere. CO₂ is believed to have been removed from the earth's atmosphere by reaction with silicate rocks, a reaction which proceeds only in the presence of water. The second is the absence of high concentrations of oxygen in the Venus atmosphere. In the earth's atmosphere, oxygen is believed to have originated in part by photodissociation of H₂O and escape of H atoms to space.

The surface of the planet is completely obscured by highly reflecting clouds whose composition is unknown. Although it is often speculated that the clouds are water droplets or ice crystals, this seems unlikely at present. The possibility that the clouds could consist, at least in part, of carbon suboxide polymer has also been considered, since it is known that such polymers are formed by the action of ionizing radiation on both CO₂ and CO.

Until recently most astronomers believed, on the basis of infrared radiometer data and the distance of Venus from the Sun, that the temperature of Venus was about the same as that of the earth, or perhaps a little higher. In the past few years, radiometer data in the microwave region have been obtained which, if interpreted as thermal radiation, lead to the conclusion that the surface temperature are very high, of the order of 600 K or higher. (The temperature of the cloud layer, however, is much lower.) None of the theories advanced to account for such a high surface temperature are very convincing and it has

TABLE 1. PLANETARY DATA*

Planet or Satellite	Distance from Sun (earth = 1)	Mass (earth = 1)	Radius (earth = 1)	Temperature (black-body av) (°K)	Density (g/cc)	Period of Revolution	Period of Rotation	Escape Velocity (km/sec)
Mercury	0.3871	0.0543	0.39	443	5.05	88 days	88 days	4.3
Venus	0.7233	0.8136	0.973	262	4.88	224.7 days	224.7 days	10.4

* Data in the first five columns are taken from Urey's¹ article. The values in the last column are those given by Kuiper.²

TABLE 2. CONSTITUENTS OF PLANETARY ATMOSPHERES*†

Planet or Satellite	Constituent	Amount (NTP-earth)†† (cm-atm)	Remarks
Venus	CO ₂	100 000	Observed spectroscopically
	N ₂		Believed major constituent from cosmic abundances
	CO	< 100	Spectroscopic upper limit
	O ₂	< 100	" " "
	CH ₄	< 20	" " "
	N ₂ O	< 100	" " "
	NH ₃	< 4	" " "
Earth	N ₂	625 000	
	O ₂	168 000	
	Ar	7 400	
	CO ₂	200	
	CH ₄	1.2	
	O ₃	0.3	
	H ₂ O	Variable	
Mars	CO ₂	3 600	Observed spectroscopically
	N ₂	180 000	Calculated from total pressure, believed major constituent
	H ₂ O		Believed present in trace amounts
	CH ₄	< 10	Spectroscopic upper limit
	NH ₃	< 2	" " "
Jupiter	CH ₄	15 000	Observed spectroscopically
	NH ₃	700	
	H ₂	$2.7 \cdot 10^7$	Calculated by Urey ¹ from cosmic abundances; based on low density of planet
	He	$5.6 \cdot 10^6$	
	N ₂	$4 \cdot 10^3$	
	Ne	$1.7 \cdot 10^4$	
	CH ₄	35 000	Observed spectroscopically
Saturn	NH ₃	200	
	H ₂	$6.3 \cdot 10^7$	Calculated by Urey ¹ from cosmic abundances; based on low density of planet
	He	$1.3 \cdot 10^7$	
	N ₂	$9.5 \cdot 10^3$	
	Ne	$2.7 \cdot 10^4$	
	CH ₄	220 000	Observed spectroscopically
Uranus	H ₂	$4.2 \cdot 10^6$	H ₂ observed spectroscopically
	He	$8.6 \cdot 10^5$	Abundances calculated by Urey ¹
	N ₂	$4.2 \cdot 10^6$	
	CH ₄	370 000	Observed spectroscopically
Neptune	H ₂		Detected spectroscopically at higher intensity than Uranus
	N ₂		
	He		
	CH ₄	20 000	Observed spectroscopically
Titan	NH ₃	< 300	Spectroscopic upper limit

* Data taken from Urey¹ and Kuiper.²

† No constituents are listed for Mercury which has no atmosphere.

†† One cm-atm (NTP-earth) is an amount of gas equivalent to a column 1 cm in height at normal atmospheric pressure and temperature.

been suggested that the microwave radiation originates from a nonthermal source such as thunderstorms, chemical reactions in the atmosphere, or electrical charge fluctuations carried on atmospheric dust particles. Many detailed discussions have been published of the lower atmosphere of Venus, including temperature variations, pressure, height and thickness of the cloud layer, and relative abundance of atmospheric constituents. Which, if any, of these is correct can be decided only after more information becomes available.

Because of the obscuring cloud layer, no surface features of the planet can be observed and the period of rotation cannot be determined by the usual astronomical methods. However, from radar data and the absence of a strong magnetic field, as found by Mariner II, it appears very likely that Venus, like Mercury, has a period of rotation equal to its period of revolution, and thus may have one permanently dark side. If this is so, the dark side may be very cold, although atmospheric convection may provide a means of warming. Infrared radiometer data show that

the cloud layer temperature of the dark side is not substantially different from that of the bright side. Many questions obviously remain to be answered about this planet which in so many ways is the earth's "twin."

The atmosphere of our own planet, *earth*, has been the subject of many extensive studies for years and a great deal of information has been gathered. The major atmospheric constituents are nitrogen and oxygen in a 4:1 ratio. Other minor constituents include CO_2 , H_2O , and Ar. Hydrogen and helium can escape from the earth's atmosphere and over geologic ages would have disappeared. The variation of pressure with altitude follows the exponential equation

$$P = P_0 e^{-\mu g h / RT}$$

where μ is the average molecular weight and g is the acceleration due to gravity. The quantity $RT/\mu g$ is called the scale height and given the symbol H . This relationship is only approximately correct because neither μ or T is constant throughout the atmosphere. For very correct calculations, changes in g must also be considered. The earth's atmosphere shows an interesting variation of temperature with altitude which arises from several factors. The earth's atmosphere is transparent to most solar radiation, which penetrates to the earth's surface and heats it to a temperature of about 290 K. The earth radiates this energy back out to space, heating the atmosphere to an extent which decreases with increasing distance from the surface. The atmospheric temperature drops gradually to 217 K at 20 km. At about 20 km, the temperature of the atmosphere begins to show changes brought about by the basic photochemistry of the atmosphere. The temperature rises to a value of about 283 K at 50 km and then decreases gradually to 168 K at 80 km. Above this altitude the temperature rises steadily to about 1500 K at 400 km and above. This maximum changes with the sunspot activity and at sunspot minimum is 1000 K.⁴

The photochemical process contributing to these variations include the following. Ultraviolet light from the sun is absorbed by O_2 molecules in the upper atmosphere, resulting in their dissociation into oxygen atoms. The atoms may then react with other O_2 molecules to form ozone

The ozone absorbs light of wavelengths below 3000 Å very strongly and, in fact, protects the earth's inhabitants from this energetic radiation. The ozone is destroyed both by this absorption of light and by further reaction with atomic oxygen

with a steady-state equilibrium being set up between formation and destruction. This occurs in a relatively narrow band at ~30 km altitude, known as the ozone layer. The energy absorbed in this narrow layer is responsible for the temperature rise. At the highest altitudes very high

energy solar radiation is absorbed, producing ions of oxygen, nitrogen, and other gases. This region is known as the ionosphere. Detailed discussions of the physics and chemistry of the earth's atmosphere have been published by Kuiper,² and Bates³ as well as others. Very extensive studies of the earth's atmosphere have been carried out in recent years using rocket probes. Much of the information obtained in this way has been summarized by Johnson¹ in the "Satellite Environment Handbook."

The atmosphere of *Mars* is relatively thin, as might be expected from the low mass and consequent low escape velocity. Urey¹ notes that over geologic ages even oxygen and nitrogen atoms may have escaped from Mars in addition to hydrogen and helium if the upper atmosphere temperature is high enough. The only atmospheric constituent identified positively is CO_2 . The total atmospheric surface pressure has been estimated by several different workers to be of the order of 1/10 that of the Earth and it is believed that nitrogen is the most abundant constituent. The Martian surface seems to have polar frost caps which disappear in summer and there is some evidence of seasonal vegetation, both of which indicate the presence of water. However, this must be in small amounts since both H-atoms and O-atoms will escape from the Martian atmosphere. Clouds are observed in the atmosphere which many conclude are water clouds. In addition a blue haze is sometimes present, whose origin is the subject of many discussions in the literature. It may be due to dust particles or to fluorescence radiation of atmospheric ions or to some other cause at present unknown. It seems improbable that oxides of nitrogen can be present in the Martian atmosphere, as recently reported, for the following reasons. Kinetic studies on the fixation of nitrogen by ionizing radiation have shown that such compounds do not form in appreciable amounts at these pressures. In addition, any small amounts formed would be destroyed by solar ultraviolet radiation.

Giant Planets. Because of their high masses and consequent high escape velocities the atmospheres of the giant planets differ substantially from those of the terrestrial planets. Hydrogen and helium cannot escape from the giant planets and, on the basis of cosmic abundance, can be expected as the major atmospheric constituents. Supporting this expectation of a reducing atmosphere, is the observed presence of a large amounts of methane in the atmospheres of all these planets and the mean molecular weight of 2.35 calculated for Jupiter from the attenuation of the atmosphere.

The atmosphere of *Jupiter* contains appreciable amounts of ammonia (700 cm-atm) in addition to an observed 15 000 cm-atm of CH_4 . Urey¹ has calculated that 2.7×10^7 cm-atm of hydrogen and 5.6×10^6 cm-atm of helium should also be present. Many colors are observed in the Jupiter atmosphere, blues, greens, yellows, and reds. Often distinct bands appear. Rice⁵ has suggested that these colors may be caused by free radicals

formed photochemically and stable at the low ambient temperatures. The most notable feature of the Jupiter atmosphere is the Great Red Spot. This unusual formation floats (in the atmosphere?) and is not rigidly attached. No satisfactory explanation has been proposed for its nature or origin. The turbulence of the cloud bands indicates that very stormy conditions prevail in the atmosphere. Recent microwave radiometer data indicate that Jupiter is surrounded by an intense radiation belt similar to the van Allen belt.

The atmosphere of *Saturn* appears to be similar in nature to that of Jupiter, with 35 000 cm-atm of methane and 200 cm-atm of ammonia being observed spectroscopically. From cosmic abundances 6.3×10^7 and 1.3×10^7 cm-atm of hydrogen and helium have been calculated by Urey.¹ Neon and nitrogen should also be expected. Colors and bands are observed in the atmosphere but they are much less pronounced than those of Jupiter. The rings of Saturn, one of the most striking features of the solar system, are believed by Kuiper² to be ice particles.

Uranus and *Neptune*, because of their high densities, appear to have different compositions, specifically, to contain smaller proportions of hydrogen and helium than do Jupiter and Saturn.¹ Ammonia has not been detected in either planet, but Kuiper² reports 220 000 and 370 000 cm-atm of methane on Uranus and Neptune respectively. The (r^1 , r^{11}) (3,0) pressure induced rotation-vibration band of H₂ has also been identified by Herzberg (see references 1 and 2). Several other spectroscopic bands have been observed which have not been positively identified to date. One band has been attributed to HNO, but it seems unlikely that this compound can be present to a significant extent.

Almost nothing is known about *Pluto* which because of its great distance from the sun, is very cold. No atmospheric constituents have been detected. This may be due to the fact that hydrogen and helium can escape and other substances except neon have no appreciable vapor pressure at this low temperature of 42°K.

Jupiter, Saturn, and Neptune all have fairly large satellites but of these only Titan, a satellite of Saturn, has a detectable atmosphere. Methane (20 000 cm-atm) is the only constituent observed.

PLASMAS

When a gas is raised to sufficiently high temperatures, the atoms and molecules of the gas become ionized since electrons are stripped off by the more violent collisions ensuing from the increased thermal agitation of the particles. In the resultant highly ionized state, the dynamical behavior of the gas can be dominated by the electromagnetic forces acting on the now unbound electrons and ions, and the properties become sufficiently different from those of the normal un-ionized gas to warrant a new name, *plasma*, to describe the gas in this highly ionized state. This name arose from the expression "plasma oscillation" coined by Langmuir to describe the very high frequency (1000 Mc/sec) longitudinal oscillations sustained by plasma in regimes where normal sound waves are characteristically strongly damped.

The modern studies of molecular, atomic, and nuclear physics had their origins in the study of the conduction of electricity through gases, and indeed, until quite recently, the (weakly) ionized gas has been used primarily to study atomic structure and the complex of collision processes—ionization, excitation, inelastic and resonant scattering, etc.—which occur when an electron strikes an atom, rather than the plasma properties (see COLLISIONS OF PARTICLES AND IONIZATION). The highly ionized plasma, with its dominant collective behavior, can be produced and observed in the laboratory only with considerable difficulty, and it is not surprising that the study of ionized gases was largely the study of atomic collision processes.

Largely due to the astrophysicist, the interest in the plasma *per se* has been revived in recent years. It was realized that the plasma state was essentially the normal state of matter in this universe. Hydrogen, which is overwhelmingly the most abundant element in the stars and space, is mostly ionized and hence totally stripped. Helium, the next most abundant element is stripped of its two electrons inside the sun and in the solar corona. Nearer home, the properties of the solar wind, Van Allen belts, and the ionosphere, demand a plasma description.

Most recently, the technological possibilities of plasma have attracted attention, most significantly in the research directed toward the controlled release of energy from the thermonuclear fusion of light elements, and it was with this stimulus that a considerable advance in the description and understanding of plasma phenomena took place. The possibilities of ionic propulsion for interplanetary flight and schemes for direct thermionic conversion have also attracted considerable attention.

We thus see that the study of the ideal plasma, a gas composed entirely of electrons and bare ions in which the inelastic atomic processes of

normal gaseous electronics are unimportant, is a subject worthy of investigation.

The problems encountered in analyzing a fully ionized plasma are of several types. Although the basic physical processes are simpler than in an ordinary gas, the motions are vastly more complicated because of the strong coupling to the electromagnetic field. From a macroscopic point of view, the plasma interacting with a strong magnetic field can often be considered, in a certain approximation, as a highly electrically conducting fluid, and thus described by a combination of hydrodynamic equations for the fluid and Maxwell's equation for the electromagnetic field. As expected, the resultant motions yield a vastly richer variety of flows than encountered in ordinary hydrodynamics and these analyses have developed into a separate discipline called *magnetohydrodynamics*, *hydromagnetics*, or **MAGNETO-FLUID-MECHANICS**.

Even in the absence of a magnetic field, the electrical properties of plasma permit complicated macroscopic motions, which involve electrostatic restoring forces and which have no parallel in ordinary gases.

From a microscopic point of view, the plasma consists of an assembly of charged particles interacting under simple inverse-square forces (and any external electromagnetic fields) and appears as an ideal subject for classical kinetic theory. However, because of the long-range character of the coulomb force, the simple picture of a diffuse gas in which the interaction can be represented as a scarce, catastrophic, binary encounter, is not valid. The microscopic dynamics of a plasma must be properly treated as a problem in many-body physics, and it is only quite recently that it has been learned how to do this in a systematic way.

The statistical many-body description of plasma may be characterized by the orders in an expansion in the parameter $\epsilon = 1/n\lambda_D^3$, where n is the average number density of particles, and λ_D , the Debye shielding distance, is given by

$$\lambda_D = [4\pi n e^2 (1 + z)/\Theta]^{-1/2}$$

Here, e is the absolute value of the electronic charge, z is the atomic number, and $\Theta = kT$ where T is the absolute temperature and k is Boltzmann's constant.*

The parameter ϵ , the inverse of the number of particles in a Debye sphere, is small and ranges, typically, from 10^{-2} to 10^{-9} ; indeed, the smallness of this parameter typifies the plasma state. The Debye length characterizes the distance over which there can be considerable departure from average charge neutrality. It measures not only the thickness of the charged sheath which forms when plasma is in contact with a solid surface, but also the effective range of the potential due to a singled-out test charge at rest

$$\phi(r) = \frac{q}{r} e^{-r/\lambda_D}$$

* Unrationalized gaussian (cgs) units are used throughout this article.

where r is the distance from the charge q . The exponential decay factor represents the average collective many-body shielding effect.

There is an important interpretation of the smallness of the plasma number ϵ . If one computes the ratio of the potential energy of interaction of one particle with its neighbor and compares it with the mean kinetic energy per particle, one finds

$$PE/KE \sim \frac{e^2 n^{1/3}}{\Theta} \sim (n\lambda_D^3)^{-2/3} \ll 1$$

Thus the effect of any one particle on a given particle is small compared to the average collective many-body effect of all its neighbors within a Debye sphere.

The average collective behavior of plasma is described (to zero order in ϵ) by the so-called Vlasov or self-consistent approximation for the density in the six-dimensional r, v phase space. The density (or one-particle distribution function) $f_s(r, v, t)$ satisfies the equation for each species s

$$\frac{df_s}{dt} + \mathbf{v} \cdot \frac{\partial f_s}{\partial \mathbf{x}} + \frac{e_s}{m_s} \left[\mathbf{E}(\mathbf{r}, t) + \frac{\mathbf{v}}{c} \times \mathbf{B}(\mathbf{r}, t) \right] \cdot \frac{\partial f_s}{\partial \mathbf{v}} + \frac{\mathbf{F}_{\text{ext}}}{m_s} \cdot \frac{\partial f_s}{\partial \mathbf{v}} = 0 \quad (1)$$

where $e_s = ze$ - ionic charge of species s , m_s is the ionic mass of species s and c is the velocity of light. \mathbf{E} and \mathbf{B} satisfy Maxwell's equations with sources

$$\sigma(\mathbf{r}, t) = \sum_s e_s \int d^3v f_s$$

and

$$\mathbf{j}(\mathbf{r}, t) = \sum_s e_s \int d^3v \mathbf{v} f_s$$

Here σ and \mathbf{j} are the average charge and current density respectively. \mathbf{F}_{ext} represents any external force field which may be present.

For undriven systems which are spatially homogeneous on the average $\mathbf{E} = \mathbf{B} = 0$, hence $\partial f / \partial t = 0$, and one must proceed to next order in the plasma number, where interaction (collisions) between pairs of *shielded* particles is considered, in order to discuss the time evolution of f .

It is observed that, in this lowest approximation, any f_0 which is a function of v alone satisfies this set of equations for the spatially homogeneous state. If one considers small departures from the spatially homogeneous situation with $f_0 = f_0(v)$ one finds the plasma capable of sustaining high-frequency, long-wavelength, plane-wave excitations of two types: longitudinal, ($\mathbf{k} \parallel \mathbf{E}$), with

$$\omega^2 \approx \omega_p^2 + 3 \frac{\Theta}{m} k^2$$

and transverse, ($\mathbf{k} \perp \mathbf{E}$), with

$$\omega^2 \approx \omega_p^2 + c^2 k^2$$

Here $\omega_p = (4\pi n e^2 / m)^{1/2}$ is the *electron plasma frequency* and m is the mass of the electron. The

much more massive ions play no role in this high-frequency situation. The electrostatic (Langmuir) oscillation actually are found to be damped, even in this collisionless approximation, by the interaction of the wave with particles traveling near the phase velocity of the wave, "Landau Damping." If the ion temperature is small compared to the electron temperature, there also exist low-frequency ion excitations in which the electrons play a quasi-static role.

The presence of a uniform magnetic field greatly increases the variety of excitations possible, but these will not be discussed here.

If the distribution f_0 is sufficiently anisotropic in velocity space, it is possible under certain circumstances, to find growing excitations. The ultimate fate of these oscillations cannot be described by the linearized theory, and a nonlinear treatment must be invoked. If the growth rate of these excitations is small, however, a "quasi-linear" or adiabatic treatment is justified and such investigations are currently very much in vogue with plasma physicists. In the presence of an external magnetic field, even small average density and temperature gradients can lead to unstable situations.

In the next order in ϵ , the effects of particle discreteness (collisions) come into play, and here one meets the kinetic theory of plasma. The relaxation to thermal equilibrium is described by a modified *Fokker-Planck* collision term which is added to the lowest order description¹ and which is characterized as a superposition of weak, statistically independent, but dynamically shielded, binary encounters. A novel addition to the usual type dissipative collisional mechanism is the emission of the forementioned longitudinal electrostatic oscillations by superthermal particles.

An interesting and important property of plasmas is their ability to radiate. At the Vlasov level of description, a spatially bounded plasma in a state of longitudinal excitation can emit transverse waves (very much like an antenna!).

To first order in ϵ , and in the presence of a magnetic field, the acceleration of charged particles in their spiraling motion about the magnetic field lines gives rise to radiation at the gyro-frequency, $\omega_c = eB/mc$, and its harmonics. These lines are not sharp, however, due to the Doppler effect of motion along the field lines, and the change in frequency due to the relativistic mass correction.

To second order in ϵ , the radiation from the particle acceleration involved in binary collisions, *bremsstrahlung*, is described.

These radiative loss mechanisms represent serious competition for the energy gain in the efforts for the controlled release of energy through the fusion of light elements.

POLAR MOLECULES

The term "polar" is applied to molecules in which there exists a permanent spatial separation of the centroids of positive and negative charge, or dipole moment. Such a moment was first postulated by P. Debye for molecules having structural asymmetry in order to explain certain of the observed electrical properties. He chose for his model an electrical dipole contained in a spherical molecule, free to rotate into alignment with an applied electric field, but subject to disorientation by collisions with other molecules due to thermal motion. At ordinary temperatures and field strengths, the electrical energy involved in the orientation is much smaller than the thermal energy kT so that only a small fraction of the dipoles are aligned with the field (k is Boltzmann's constant and T is the temperature in degrees Kelvin). The net dipole moment per mole (*molar polarizability*) is then calculated statistically to be

$$P = \frac{4\pi}{3} N \left(\alpha + \frac{\mu^2}{3kT} \right) \quad (1)$$

where μ is the permanent dipole moment per molecule, i.e., the charge multiplied by the distance of separation, and N is Avogadro's number. The polarizability α represents the induced moment per molecule resulting from the temporary distortion of the electron orbits by the applied field. For nonpolar molecules, it is the only contribution; it corresponds to the optical polarizability as measured by the refractive index.

The molar polarizability may be related to the dielectric constant ϵ by the approximate equation of Clausius and Mosotti

$$\frac{\epsilon - 1}{\epsilon + 2} \frac{M}{d} = P \quad (2)$$

where M is the molecular weight and d is the density. The permanent dipole moment of a molecule may therefore be determined by measuring the temperature coefficient of the dielectric constant as seen by combining Eqs. (1) and (2). Alternatively, a companion measurement of the optical refractive index may be made to determine α , and the dipole moment is then obtained as the difference between the total polarization and the optical contribution. The measurements are made in dilute vapor or solution phase, so that the individual dipoles are sufficiently far apart that they do not influence one another (see REFRACTION).

Equation (1) is valid in the low-frequency region where the dipoles are able to rotate in phase with the applied electric field. This rotation is subject to various restraints; in the simple case of a spherical molecule of radius a rotating in a fluid of viscosity η , this leads to a relaxation time

$$\tau = \frac{4\pi a^3 \eta}{kT} \quad (3)$$

corresponding to a frequency range of *anomalous dispersion* in which the molecules become unable to follow the oscillations of the applied field. This gives rise to an out-of-phase component of the dielectric constant representing a conductivity or *dielectric loss*, ϵ'' , i.e., a dissipation of energy in the form of heat. Mathematically this is expressed as a complex dielectric constant.

$$\epsilon = \epsilon' - j\epsilon'' \quad (4)$$

$$\epsilon' - \epsilon_\infty = \frac{\epsilon_0' - \epsilon_\infty}{1 + \omega^2 \tau^2} \quad (5)$$

$$\epsilon'' = \frac{(\epsilon_0' - \epsilon_\infty) \omega \tau}{1 + \omega^2 \tau^2} \quad (6)$$

ω is $2\pi \times$ the frequency, and the subscripts 0 and ∞ refer to dielectric constant measured at very low and very high frequency, respectively. Cole and Cole showed for polar molecules having a unique relaxation time that a plot ϵ'' vs ϵ' is a semicircle centered on the ϵ' -axis. For more complicated molecules or high polymers, the center becomes depressed below the ϵ' -axis and the curve may be further distorted. This behavior is generally characterized by a distribution of relaxation times as a result of the orientation of molecular segments of various shapes and sizes. Information regarding the freedom of orientation within the molecules may thus be gained.

These simple relationships between dipole moment and dielectric constant fail for concentrated solutions or pure polar liquids because they do not take into account the interaction of the dipoles, both permanent and induced, with one another. The calculations have been extended by Onsager, Kirkwood, and others, to include these effects. It becomes necessary to include in the theory a correlation factor which is a measure of the extent of nonrandom orientation of the dipoles, i.e., the tendency of the dipoles to aggregate parallel or antiparallel to one another. Experimental determination of this quantity yields further insight into the structure of polar liquids.

In the solid state, most crystalline polar compounds exhibit low dielectric constants because the rotational freedom necessary for dipole orientation has been frozen out. A few compounds, however, do show a persistence of high dielectric constant to temperatures below the melting point, indicating rotational freedom in the solid. At some lower temperature the rotation ceases

and the dielectric constant drops. This change in dielectric constant has frequently been used as a method of detecting second-order transitions in polar compounds.

Some success in the correlation of dipole moment with molecular structure has been achieved. A series of moments assigned to individual bonds was developed empirically by Smyth, Pauling, and others from measurements on simple molecules. They are intended for approximate calculation of dipole moments of complex molecules by vectorial addition along the bond directions as determined by other means. It is assumed that there is no interaction between bonds; this generally results in the calculated values being higher than the measured moment because of inductive effects, i.e., electrons being shared in a bond between two atoms are not wholly available to a neighboring bond, so that neither bond attains its full moment. An approximate correction for this effect has been made by Eyring and co-workers. Despite these inadequacies, the calculated moments are often helpful in determining molecular structures and have often applied in the case of various substituted benzene-ring compounds. Of special importance is the ability to decide between a polar or nonpolar, i.e., symmetrical, structure.

More detailed quantum mechanical calculations of dipole moments have been less successful. Rather the experimentally determined moments have been used to assign varying degrees of ionicity and covalency to the bonds in establishing the electronic hybridization structure. Quantum mechanics has also shown how it is possible to obtain extremely accurate measurements of the dipole moments from spectroscopic Stark splittings.

POLARIZED LIGHT

Polarized light is an especially simple form of light and can be defined easily in terms of either of the two prevalent theories of light: the wave theory and the photon theory (see LIGHT). According to the former, light consists of trains of electromagnetic waves whose wavelengths lie in the range from about 4×10^{-7} to 7×10^{-7} meters. A noteworthy feature of the waves is that two kinds of displacements are involved: electric and magnetic. Another significant feature is that, when the waves are traveling in empty space (or in glass, water, or other isotropic medium) the electric and magnetic displacements are perpendicular to the direction of propagation of energy; i.e., they are transverse, not longitudinal. Since the electric and magnetic displacements are always perpendicular to one another and have equivalent magnitudes, it is sufficient to specify just one of these quantities; most

authors choose to deal with the electric displacement.

Consider, now, a slender beam of light that is traveling east, i.e., from left to right in Fig. 1. If it happens that the direction of electric displacement is everywhere up or down, but not north or south, the beam is said to be linearly polarized in the vertical plane. If, alternatively, the displacements were north and south, the beam would be called *horizontally* linearly polarized. The displacement might, of course, lie in some tilted plane specified by an angle α ; in such case, any given displacement may be regarded as the resultant of a vertical displacement and a horizontal displacement. The *sectional pattern* of any such beam is conventionally indicated by a straight line segment at the appropriate azimuth α , as indicated in Fig. 2(c). Linearly polarized beams that have azimuths differing by 90° are said to have *orthogonal* polarization forms.

Circular and elliptical polarization forms exist also. Circularly polarized light may be regarded as the result of combining two linearly

FIG. 1. Monochromatic beam of wavelength λ traveling horizontally to the right. Since, in this example, the electric displacement is vertical, the sectional pattern (indicated at right) consists of a vertical line and the beam is said to be vertically linearly polarized. The observer is situated far to the right, facing the light source.

FIG. 2. Variety of sectional patterns of polarized light: (a) horizontally polarized; (b) vertically polarized; (c) linearly polarized at azimuth α ; (d) right circularly polarized; (e) left circularly polarized; (f) right elliptically polarized at 45° azimuth and with ellipticity, or ratio of semi-axes, of approximately 3.

polarized beams that have the same wavelength and same intensity, are polarized in orthogonal directions (e.g., horizontal and vertical) and differ in phase by $1/4$ cycle, or 90° . If the horizontally polarized component *lags* in phase by 90° , the sectional pattern of the combined beam is drawn as a circle executed clockwise, as judged by an observer facing towards the light source. If the horizontally polarized component *leads* by 90° , the circle has a counterclockwise sense and the light is called left circularly polarized. In the general case, the components may differ in magnitude and the phase difference may have any value; the general sectional pattern is an ellipse.

A different description of polarized light is required when the light is regarded as a stream of photons. This is the case when the photons are so infrequent and so energetic that they can be detected individually. In such case, it is the spin, i.e., the angular momentum, of the photon that constitutes the polarization. A right circularly polarized photon has a spin of $+1$ unit, and a left circularly polarized photon has a spin of -1 unit. Theory and experiment are in agreement that the magnitude of the unit in question is $h/2\pi$, where h is Planck's constant (see QUANTUM THEORY). Linearly and elliptically polarized photons may be regarded as combinations, in suitable proportions, of positive and negative spins.

Unpolarized light is more complex than polarized light, hence it is harder to describe. It consists of light in which the azimuth, ellipticity, and handedness of polarization vary rapidly and at random, so that no one type of polarization predominates. No simple diagram can depict the chaos and impartiality of the sectional pattern. If, in a given beam, one particular sectional pattern slightly outweighs all other patterns, the beam is said to be partially polarized; the degree of polarization may lie anywhere in the range from 0 to 100 per cent.

Polarization is not confined to visible light, but applies also to longer-wavelength radiations including the infrared and radio ranges and to shorter-wavelength radiations including ultraviolet light and x-rays. Nevertheless, the visual range deserves special attention in view of the variety of phenomena observed and the nicety of observation and wealth of applications.

Polarization was discovered by the Dutch scientist Christian Huygens in 1690, but it was not well understood until the transverse nature of the vibration, suggested by the English physicist Robert Hooke in 1757, was confirmed by Thomas Young in 1817. Further clarification came in 1873 when Maxwell showed that light waves belong to the family of electromagnetic waves.

Today many simple methods of producing polarized light are known. Usually, an investigator starts with a beam of unpolarized light and then polarizes it by inserting a suitable optical device—a polarizer. However, the invention of the LASER makes it feasible to generate light that

is polarized from the outset; no polarizer is needed. Various natural sources of polarized light exist, e.g. rays of light from a portion of the blue sky that is viewed in direction at 90° to the direction of the sun, also light from certain distant galaxies, such as the Crab nebula.

Conceptually, the simplest polarizer is the *micro-wire grid*, which consists of an array of parallel metallic wires each of which is less than a wavelength in diameter and is separated from its neighbors by comparably small distances. When a beam of unpolarized light strikes the grid, the component of the electric vibration that is perpendicular to the wires passes through readily, while the component that is parallel to the wires induces electric currents along them and is reflected or absorbed. The transmission axis of the device, defined in terms of the electric vibration of the transmitted component, is perpendicular to the wires. A far more economical type of polarizer is one that employs long, thin absorbing molecules, rather than wires. The most popular of the commercially produced polarizers, called H-sheet, contains large numbers of long, thin polymeric molecules consisting mainly of iodine atoms. These molecules are embedded in a plastic film that has previously been stretched unidirectionally so as to have a pronounced "grain"; the long slender molecules of iodine conform to this grain. Polarizers containing small absorbing units (whether wires or molecules) that show markedly different extents of absorption for different directions of electric vibration in the incident beam are called *dichroic* polarizers.

The first highly efficient polarizer was of birefringent type: it was made of the crystal *calcite* ($\text{CaO} \cdot \text{CO}_2$) which has two refractive indices and thus divides any incident beam into two beams. Each of these is linearly polarized, and the sectional patterns are orthogonal. Usually the crystal is artificially shaped so that one of the polarized beams is transmitted straight ahead and the other is deviated and disposed of by total internal reflection. The calcite prism designed by the Scottish physicist Nicol in 1828 was a basic piece of equipment in optics laboratories for over a hundred years. Types devised subsequently by Wollaston, Ahrens, and Foucault have proven to be superior in several respects.

Polarizers of reflection type are also well known. A typical reflection polarizer consists of a plate of glass that is mounted obliquely in the given beam of unpolarized light. The component that is transmitted is found to be partially polarized, and the reflected component is even more highly polarized—with the orthogonal sectional pattern. If the obliquity of the incident beam (measured from the normal to the plate) corresponds to *Brewster's angle*, defined as the angle that has a tangent of n , where n is the refractive index of the plate, the reflected beam is 100 per cent polarized. For ordinary glass, n has the value 1.5 and Brewster's angle is about 56° . Polarization by reflection is of common occurrence; yet few persons are aware of it; they are

unaware, for example, that light reflected obliquely from the surface of a pond, a wet road, or a glossy sheet of paper is partially linearly polarized.

Asymmetric scattering is another process that polarizes light. The polarization observed in light from the blue sky is a consequence of scattering of the sun's rays, especially the short-wavelength or blue component thereof, by the molecules of the air.

Perhaps the simplest application of polarizers is in controlling the intensity of a light beam. For this purpose two polarizers are used, in series. If they are oriented so that their transmission axes are parallel to one another, the over-all transmittance is large. If they are oriented so that the two axes are crossed, i.e., at an angle $\theta = 90^\circ$ to one another, the transmittance is zero; the beam is said to be extinguished. For intermediate angles-of-crossing the transmission is easily calculated from Malus' law, which affirms that the transmittance is proportional to $(\cos \theta)^2$. If the incident beam is already polarized, a single polarizer suffices to reduce the intensity to any desired extent. Polarizing sunglasses are effective in this manner thanks to the fact that light reflected obliquely from roads and most other nearly horizontal surfaces is partially *horizontally* polarized; since the polarizer lenses of the sunglasses are oriented with their transmission axes *vertical*, much of this reflected "glare" light is blocked. A polarizer that is employed to block an already polarized beam is called an analyzer.

Much of the interest in polarized light stems from the surprising convertibility of polarization form. By interposing an appropriate retardation plate, or *retarder*, in a given polarized beam, an experimenter can alter the polarization form at will, and with almost 100 per cent efficiency. A typical retarder consists of a thin flat crystal that exhibits birefringence, i.e., has two different refractive indices. Mica, being birefringent and being easily cleaved into thin plates, is often used. When a beam of polarized light enters a plate of mica, the beam is divided into two components and the phases of these are affected ("retarded") to different extents; thus when the components emerge from the plate and unite to form a single beam again, this latter is found to have a drastically altered sectional pattern. Especially versatile and accurate control of polarization form can be achieved with retarders of calcite or quartz. The effect of any given retarder on any given beam can be predicted accurately by various conventional means and, more recently, by a matrix algebra perfected by the American scientist Hans Mueller; the procedure is to multiply the four-element vector representing the beam by the sixteen-element matrix representing the retarder. Since the vectors and matrices are tabulated in various books, the procedure entails little effort; indeed it is readily extended to cases in which there are several retarders arranged in series. In cases where high accuracy is not needed, predictions can be made

especially rapidly with the aid of a kind of map, or spherical slide-rule, called the Poincaré sphere after its inventor Henri Poincaré.

When an object of glass or transparent plastic is subjected to a unidirectional stretching or compressing force, it becomes birefringent and thus acts like a retarder. Accordingly an engineer who wishes to evaluate the unidirectional strain within such an object can do so by directing a beam of polarized light through it and, with the aid of a calibrated retarder and an analyzer, measuring the change in the sectional pattern of the beam. Using conversion factors published in books on photoelastic analysis, he can interpret the change in terms of the direction and magnitude of the strain (see PHOTOELASTICITY).

Many microscopic biological objects, such as components of living cells, appear transparent and virtually invisible under a microscope. Yet such components often contain groups of aligned birefringent molecules and thus are capable of acting like miniature retarders. If the biologist illuminates a living cell with polarized light and examines it under a microscope that is equipped with an analyzer, he finds the birefringent components to be highly visible. Thus the use of polarizers renders visible a microscopic world that is normally invisible. Similarly, mineralogists find that the polarizing microscope greatly increases the visibility of small birefringent crystals.

There are many other applications of polarizers. Photographers use them to increase the contrast between white clouds and the (polarized) blue sky. Chemists use them to measure the extents to which various liquid solutions rotate the sectional pattern of a linearly polarized beam; the extent of rotation is a measure of the concentration of the solution. Electronics engineers use circular polarizers to trap and thus eliminate reflected glare from radar screens. Illumination engineers have devised systems of polarizing filters for automobile headlights and windshields that eliminate glare in nighttime driving. Biologists have found that the direction of growth of certain algae can be controlled by illuminating the algae with polarized light of controlled sectional pattern. Bees and ants can detect linear polarization directly by eye, and they employ the polarization of blue sky light as a navigational aid. Even man can learn to detect the polarization of white light with the naked eye, and he can also distinguish right from left circularly polarized light.

Physicists use polarizers to study the emission of polarized light by atoms situated in regions of strong electric or magnetic field, to determine the strength of the sun's magnetic field by measuring the polarization of certain solar spectral lines, and to determine the pattern of magnetic fields within the Crab Nebula. They use polarizers to analyze the behavior of the remarkable light source *the laser* and to verify theoretical predictions as to the polarization inherent in the synchrotron radiation emitted by certain high-energy accelerators.

Because of light's puzzling dual character (waves and photons) and its central position in the growing field of physics, and because *polarized* light is a most elemental form of light, physicists are confident that polarized light will continue to be an outstandingly challenging enigma as well as a most versatile tool for many generations to come.

POLARON

An electron in the conduction band of an insulator (or a hole in the valence band) polarizes the medium in its neighborhood—this effect is particularly important in ionic crystals, on account of their high polarizability. The name "polaron" is given to the electron together with its associated cloud of lattice polarization. The subject has been of interest since Landau¹ suggested that an electron could become self-trapped by the lattice polarization it induces; this would mean that its effective mass would be very large compared with its "bare" mass (as given by band theory).

Frohlich, Pelzer and Zienau² have proposed a simple model Hamiltonian for the polaron. They assume that the ionic medium can be represented by a set of harmonic oscillators. Each oscillator is characterized by a wave vector \mathbf{q} , but the frequency ω is simply related to the Reststrahl frequency ω_r , and does not depend on \mathbf{q} . If \mathbf{p} is the electron momentum and \mathbf{r} its position, m the band mass, $\sigma_{\mathbf{q}}$ and $\sigma_{\mathbf{q}}$ canonical creation and annihilation operators for oscillator quanta ("optical phonons"), and Ω is the normalization volume, then the Hamiltonian is

$$H = -\frac{1}{2}\nabla^2 + \sum_{\mathbf{q}} \sigma_{\mathbf{q}}^{\dagger} \sigma_{\mathbf{q}} + i \left(\frac{2\sqrt{2}\pi\alpha}{\Omega} \right)^{\dagger} \sum_{\mathbf{q}} (\sigma_{\mathbf{q}}^{\dagger} e^{-i\mathbf{q}\cdot\mathbf{r}} - \sigma_{\mathbf{q}} e^{i\mathbf{q}\cdot\mathbf{r}}) \quad (1)$$

in units such that the electron band mass $m = 1$, $\hbar = 1$, and $\omega = 1$. The parameter α is defined as

$$\alpha = \frac{e^2}{\hbar} \left(\frac{1}{\epsilon_{\infty}} - \frac{1}{\epsilon_0} \right) \sqrt{\frac{m}{2\hbar\omega}} \quad (2)$$

with ϵ_∞ the frequency-dependent dielectric constant.

The theory, as so far formulated, is one of a particle interacting in a very simple way with a (nonrelativistic) field—the only parameter is the dimensionless coupling constant α . The problem is therefore of fundamental field-theoretical interest, as well as being interesting for its applications.

For very small α ($\alpha \leq 1$), a perturbation-theoretical and a Tamm-Dancoff type of variational calculation agree that Landau self-trapping does *not* occur.² For rather larger α ("intermediate coupling", $\alpha \leq 5$), the canonical transformation of Lee, Low and Pines,³

$$\left. \begin{aligned} \alpha_{\mathbf{q}}' &= (\alpha_{\mathbf{q}} + i c_{\mathbf{q}}) e^{-i \mathbf{q} \cdot \mathbf{r}} \\ \alpha_{\mathbf{q}}^{*'} &= (\alpha_{\mathbf{q}}' - i c_{\mathbf{q}}) e^{i \mathbf{q} \cdot \mathbf{r}} \\ \mathbf{p}' &= \mathbf{p} + \sum_{\mathbf{q}} \hbar \mathbf{q} \alpha_{\mathbf{q}}^{*'} \alpha_{\mathbf{q}} \\ \mathbf{r}' &= \mathbf{r} \end{aligned} \right\} \quad (3)$$

partially decouples the electrons from the phonons and extends the perturbation-theoretical results. The binding energy (in units of $\hbar\omega$) is

$$E_0 = -\alpha + O(\alpha^2) \quad (4)$$

and the effective mass

$$m^* = 1 + \frac{1}{6}\alpha \quad (5)$$

The result confirms the view of Fröhlich, Pelzer and Zienau² that self-trapping does not occur in, for example, the alkali halides ($\alpha \approx 5$ for NaCl).

For very large α ("strong coupling", $\alpha \gtrsim 10$), a variational treatment by Pekar⁴ *does* lead to very large effective masses; he finds

$$E_0 \approx -0.10\alpha^2 \quad (6)$$

$$m^* \approx 230(\alpha/10)^4 \quad (7)$$

However, for intermediate values of α , neither method is very good. A method due to Feynman⁵ provides a "bridge" between the strong- and intermediate-coupling regimes. The electron propagator (for states with no free phonons) is expressed as an integral over all possible paths of the exponential of an action functional. The oscillator coordinates do not appear explicitly, but the action contains a term which represents an interaction of the electron *with itself at earlier times*, through a Coulomb potential:

$$\langle \mathbf{r}_1 t' | \mathbf{r}_2 t'' \rangle = \int \mathcal{D} \mathbf{r}(t) e^S \quad (8)$$

$$S = - \int_{t'}^{t''} \frac{1}{2} \dot{\mathbf{r}}^2 dt + \frac{\alpha}{2} \iint_{t'}^{t''} dt_1 dt_2 \frac{\exp - (t_1 - t_2)}{|\mathbf{r}(t_1) - \mathbf{r}(t_2)|} \quad (9)$$

[For convenience, we use an imaginary time variable.]

Feynman makes the variational ansatz for the action

$$S_0 = - \frac{1}{2} \int_{t'}^{t''} \dot{\mathbf{r}}^2 dt - C \iint_{t'}^{t''} dt_1 dt_2 (\mathbf{r}(t_1) - \mathbf{r}(t_2))^2 \exp - w(t_1 - t_2) \quad (10)$$

where C and w are parameters to be determined. This trial functional is the exact action for a model system in which the electron is coupled to a fictitious particle of mass $M = \frac{4C}{w^3}$ through a

spring constant $K = \frac{4C}{w}$, after the coordinates of the fictitious particle have been eliminated. An upper bound for the energy can be derived:

$$E = \frac{3}{4} \frac{(v - w)^2}{v} - \frac{\alpha}{\sqrt{\pi}} \frac{v}{w} \int_0^\infty dt e^{-t} \left\{ t \left(1 + \frac{v^2 - w^2}{vw^2} \left[\frac{1 - e^{-vt}}{t} \right] \right) \right\}^{-1} \quad (11)$$

where $v^2 = (4C/w) + w^2$. Equation (11) then has to be minimized with respect to w and v . In the limits $\alpha \lesssim 3$, $\alpha \gtrsim 10$, it reduces to the Lee-Low-Pines³ and Pekar⁴ solutions respectively, but for intermediate values E has had to be evaluated numerically⁵. The effective mass and the mobility have also been calculated, and vary smoothly with α .

When α is very large, the radius of the polaron becomes small. A measure of the radius, R , is the amplitude of zero-point oscillation of the two-particle model system,

$$R \sim \left(\frac{v^2 - w^2}{3v} \right)^{-1} \quad (12)$$

For large α , R is found to be $\approx \alpha^{-1}$. Since the unit of length, $\sqrt{\hbar/mw} \sim 10\text{\AA}$, R can become less than the lattice spacing; the continuum model must then break down. In this case (the "small" or "localized" polaron), Fröhlich and Sewell⁷ showed that the appropriate model is a Bloch tight-binding one; the overlap integrals between polaron wave functions localized on adjacent lattice sites are assumed small. The polaron mass is then very large. Conduction at finite temperatures occurs largely by the electron "hopping" from one site to another—the jump frequency is related to the overlap integrals.

Experimental tests of polaron concepts have been limited mainly by the difficulty of measuring the "bare" mass m , and hence of knowing the value of α . However, recent experiments by F. C. Brown⁸ and his collaborators have largely succeeded in "disentangling" the parameters. They have compared the "Hall" mobility μ_H (defined as cR/ρ , where R is the Hall coefficient and ρ the resistivity) with the Ohmic or "drift" mobility μ ; using the theory of Feynman *et al.*,⁸ they are able to find explicit values of m , m^* and α . They have also observed cyclotron resonance of charge carriers in an ionic medium;

this gives an independent estimate of m^* . In principle, one should be able to measure m by looking at a cyclotron resonance *above* the Reststrahl frequency, but this has not yet proved possible.

POLYMER PHYSICS

Polymers are long-chain molecules with molecular weights of from thousands to many millions (generally between 20,000 and 10^7 for materials of practical interest). The molecules may be linear, branched, or cross-linked to give a gel structure.

The size and shape of polymer molecules are generally determined from measurements in dilute solution. Molecular weights are obtained from osmotic pressure (number average molecular weight), light scattering (weight average molecular weight), and intrinsic viscosity measurements. Dissymmetry of light scattered by dilute solutions gives the size of molecules. Extent of chain branching can be estimated from light scattering or solution viscosity measurements by comparing the branched polymer with a linear polymer of the same molecular weight. The degree of cross-linking can be determined from the extent of swelling in a solvent or from the elastic modulus by using the kinetic theory of rubber. Swelling decreases and modulus increases as cross-linking increases. Solution properties are not only sensitive to molecular weight but also to the interaction between the polymer and solvent molecules. Most polymers have a distribution of molecular weights. In addition to the results from fractionations, the width of the distribution can be estimated from the ratio of

weight average to number average molecular weights. This ratio is 1.0 if all the molecules are the same; it is around 2 for most polymers, but may be much greater for some highly branched polymers.

The molecular structure of polymers is unusually complex since the molecules can assume many conformations; more than one type of monomeric unit can make up the chains to give an infinite variety of distribution of sequence lengths, or the monomeric units can be arranged in different types of stereoregularity—isotactic, syndiotactic, or atactic forms. Nuclear magnetic resonance and infrared spectroscopy are especially powerful techniques for studying the structure of polymers. For polymers capable of crystallizing, x-ray diffraction is another useful tool.

The most important quantity determining the mechanical and many other physical properties of polymers is the glass transition temperature. If the glass transition temperature, T_g , is below ambient temperature, the molecules have extensive freedom of movement, so the material is either a viscous liquid or a rubbery material with a low elastic modulus. If T_g is above ambient temperature, the movement of the molecules is frozen-in, so that the polymer is a rigid solid with a high elastic modulus of the order of 10^{10} dynes/cm². The glass transition temperature is not sharply defined but depends to some extent on the time scale of the experiment—the faster the experiment, the higher is the apparent T_g . Glass transitions may be measured by many techniques such as where breaks occur in the slope of volume or refractive index vs temperature curves or by the rapid change in elastic modulus with temperature in the transition region. The position of T_g on the temperature scale is largely due to the stiffness of the polymer chains. Flexible molecules such as polybutadiene and silicone rubbers have low T_g , while stiff molecules such as polystyrene and polymethyl methacrylate have high transition temperatures. Cohesive energy density or polarity is another important factor in determining T_g . Symmetry plays a secondary role. Glass transitions can be regulated by copolymerization or by addition of a plasticizer which lowers T_g .

Many polymers including polyethylene and isotactic polypropylene are semicrystalline. In their bulk behavior such polymers behave as though they are a mixture of amorphous and crystalline materials, but the exact nature of the crystalline state is not yet clearly defined for such materials. In the crystal lattice, some types of polymer chains assume a zig-zag conformation while others crystallize in the form of helices. Single crystals of some polymers have been grown from dilute solutions. In these single crystals the chains are perpendicular to the faces making up the thin lamellar crystals, so that each polymer chain must fold back on itself several times. There is some morphological evidence, based on electron microscopy studies, that even in the bulk polymer cooled down from the melt there

is extensive chain folding in the crystalline phase. In terms of a two-phase model, the degree of crystallinity may be determined by x-ray, density or heat capacity measurements. Different techniques generally give similar but not identical values for the degree of crystallinity; typical values vary from 40 per cent crystallinity for low-density polyethylene to 85 per cent for high-density polyethylene. Crystallinity is greatly affected by chain perfection. Copolymerization and branching greatly reduce crystallinity. Highly stereoregular polymers such as isotactic polystyrene tend to be crystalline, while the random atactic polymers are noncrystalline. The melting point also depends upon chain perfection—the greater the degree of imperfection, the lower is the melting point.

Many polymers of commercial importance are not linear polymers consisting of a single type of monomeric unit. Copolymers contain two or more kinds of monomers. If one type of monomer makes up the backbone and another type side chains, the polymers are called graft polymers. If two polymers are mechanically mixed together, the mixture is called a polyblend. Most, but not all, polyblends are two-phase systems.

Even at higher temperatures where linear polymers are liquid, they tend to be very viscous. The melt viscosity is especially high if the molecular weight is above a critical value where chain entanglements can occur. At molecular weights above which entanglements occur, the melt viscosity at low rates of shear depends approximately on (molecular weight)³⁻⁴. These viscous polymer melts are also more or less elastic in nature and behave somewhat like rubber. If the molecules are cross-linked to one another, the elastic behavior becomes dominant and true vulcanized rubbers result. Polymer melts are generally non-Newtonian, and the properties are very dependent upon the rate of shear. Molecular theories have been developed by Rouse, Zimm, and Bueche which explain quite well many of the rheological properties of melts and solutions.

The usefulness of polymers depends primarily upon their mechanical properties. The elastic modulus of rubbers is explained quite satisfactorily by the kinetic theory of rubber elasticity. No satisfactory theory is yet available for rigid polymers. Dynamic mechanical measurements using oscillating stresses or strains have been especially useful in relating mechanical properties to molecular structure; such tests are generally made to measure the elastic modulus and mechanical damping over a wide range of frequencies and temperatures. Generally the effects of temperature and frequency (or time) can be made equivalent by a superposition treatment such as developed by Williams, Landel, and Ferry. The phenomenological theory of viscoelasticity has developed to the stage where it is possible to interconvert data from one type of test (say dynamic mechanical) to other types of tests such as creep, stress relaxation and, to a lesser extent, stress-strain data. On heating a rigid organic polymer, the modulus drops from about 10^{10}

dynes/cm² to a low value of about 10^7 dynes/cm² in a small temperature interval near the glass transition temperature, unless the polymer is highly cross-linked or crystalline. Both crystallinity and cross-linking can greatly increase the modulus above T_g , but they have little effect on the modulus below T_g . Polymers are unique in that some of them can be elongated over 1000 per cent before they break.

The dielectric constant and power factor or electrical loss depend upon the number and type of dipoles. At low temperatures (or high frequencies) where the dipoles are frozen-in, the dielectric constant and electrical loss are both low. At high temperatures (or low frequencies) where the molecules have high mobility, the dielectric constant is high while the electrical loss is often low. At intermediate temperatures or frequencies where the main relaxation times for dipolar motion are approximately the same as the applied electrical frequency, the electrical loss goes through a pronounced maximum, and the dielectric constant changes rapidly with either frequency or temperature. Since the mobility of the chain backbone is related to the ease with which dipoles can move, there is often a good correlation between electrical and mechanical properties. Impurities in polymers can be very detrimental to good electrical properties, especially at high temperatures where conductivity can be relatively high.

Most pure amorphous polymers are transparent. Crystallinity often makes a material milky or white in appearance. Long chain molecules can be oriented by stretching in the molten state or by cold-drawing in some cases. Such oriented materials are generally highly birefringent, since the polarizability along the chain is usually quite different from the polarizability perpendicular to the chain. The mechanical properties of oriented polymers are also highly anisotropic. For instance, the modulus and tensile strength are generally much greater parallel to the chain axis than perpendicular to it.

Polymers have very high coefficients of thermal expansion compared to most rigid materials. The coefficient of expansion shows a distinct break at the glass transition temperature—the coefficient being greater above T_g . Most polymers would be classed as thermal insulators rather than as thermal conductors.

POSITIVE RAYS. *See* ISOTOPE

POSITRON

The positron is one of many fundamental bits of matter. Its rest mass (9.109×10^{-31} kg) is the same as the mass of the electron, and its charge ($+1.602 \times 10^{-19}$ coulomb) is the same magnitude but opposite in sign to that of the electron. The positron and electron are antiparticles for each other. The positron has spin 1/2 and is described by Fermi-Dirac statistics as is the electron (see ELECTRON).

The positron was discovered in 1932 by C. D. Anderson at the California Institute of Technology while doing cloud chamber experiments on cosmic rays. The cloud chamber tracks of some particles were observed to curve in such a direction in a magnetic field that the charge had to be positive. In all other respects, the tracks resembled those of high-energy electrons. The discovery of the positron was in accord with the theoretical work of Dirac on the negative energy states of electrons. These negative energy states were interpreted as predicting the existence of a positively charged particle.

Positrons can be produced by either nuclear decay or the transformation of the energy of a gamma ray into an electron-positron pair. In nuclei which are proton-rich, a mode of decay which permits a reduction in the number of protons with a small expenditure of energy is positron emission. The reaction taking place during decay is

where p^+ represents the PROTON, n^0 the NEUTRON, e^+ the POSITRON, and ν a massless, chargeless entity called a NEUTRINO. The positron and neutrino are emitted from the nucleus while the neutron remains bound within the nucleus. An example of such a nuclear decay is

This particular decay provides a practical, usable source of positrons for experimental purposes.

The process of pair production occurs when a high-energy gamma ray interacts in the electromagnetic field of a nucleus to create a pair of particles—a positron and an electron. Pair production is an excellent example of the fact that the rest mass of a particle represents a fixed amount of energy. Since the rest energy ($E_{\text{rest}} = m_{\text{rest}}c^2$) of the positron plus electron is 1.022 MeV, this energy is the gamma energy threshold and no pair production can take place for lower-energy gammas. In general, the cross section for pair production increases with increasing gamma energy and also with increasing Z number of the nucleus in whose electromagnetic field the interaction takes place.

The positron is a stable particle (i.e., it does not decay itself), but when it is combined with its antiparticle, the electron, the two annihilate each other and the total energy of the particles appears in the form of gamma rays. Before

annihilation with an electron, most positrons come to thermal equilibrium with their surroundings. In the process of losing energy and becoming thermalized, a high-energy positron interacts with its surroundings in almost the same way as does the electron. Thus for positrons, curves of distance traversed in a medium as a function of initial particle energy are almost identical with those of electrons.

It is energetically possible for a positron and an electron to form a bound system similar to the hydrogen atom, with the positron taking the place of the proton. This bound system has been given the name "positronium." The energy levels of positronium are about one-half those of the hydrogen atom since the reduced mass of positronium is about one-half that of the hydrogen atom. This also causes the radius of the positronium system to be about twice that of the hydrogen atom. Thus positronium is a bound system with a radius of 1.06 Å and a ground state binding energy of 6.8 eV. As mentioned previously, the positron has an intrinsic magnetic moment and an intrinsic angular momentum, or spin. In positronium, the spins of the electron and positron can be oriented so they are either parallel or antiparallel. These two states, called ortho-positronium and para-positronium respectively, have very different annihilation characteristics. Most positrons entering a medium do not form positronium, but the general annihilation characteristics show the same dependence on orientation of the spins, regardless of whether the annihilation occurs in a collision or from the bound state.

It is possible for a positron-electron system to annihilate with the emission of one, two, three, or more, gamma rays. However, not all processes are equally probable. One-gamma annihilation requires another particle to participate to conserve momentum. This process is a very infrequent type decay. The most probable decay is by the emission of two gamma rays, directed in opposite directions, with each possessing about one-half the energy of the system. The presence of these 0.511-MeV ($=m_e c^2$) gamma rays is always found when positrons are present. Whether annihilation is to be by the emission of one, two or three gammas depends on the orientation of the spins of the positron and electron. Conservation of angular momentum requires that the decay be by two-gamma emission if the spins are antiparallel, and by three-gamma (or one-gamma) emission if the spins are parallel.

If formed in free space, positronium exhibits two characteristic lifetimes against self-annihilation. These are $\tau_1 = 1.25 \times 10^{-10}$ second for the antiparallel spin case (also called the singlet state) and $\tau_3 = 1.39 \times 10^{-7}$ second for the parallel spin case (called the triplet state). Another lifetime, characteristic of the physical surroundings of the positron, is found when positronium is formed in certain condensed materials. This lifetime (known as τ_2) is longer than the singlet free space lifetime τ_1 , but is much shorter than

the triplet free space lifetime τ_3 . In general, this τ_3 lifetime is a measure of the rate of "pickoff" of atomic electrons with antiparallel spins by the positrons in triplet positronium. In this process, the positron enters the material and forms triplet positronium with an electron, but then annihilates with an electron belonging to one of the surrounding atoms, whose spin is oriented opposite to that of the positron. That the probability of "pickoff" and the subsequent two-gamma annihilation depend on the properties of the surroundings is to be expected. Indeed, the τ_3 lifetime is a function of the material, the temperature, the density, the degree of crystallinity, the phase, etc.

The angular correlation of the annihilation gammas has been measured for both the two-gamma and three-gamma cases. In three-gamma annihilation, the gammas are coplanar as predicted, and azimuthally correlated such that their energies and directions are consistent with the conservation laws of energy and momentum. Two-gamma annihilation studies have been extensive, the results showing that the two gammas are emitted within a few milliradians of 180° from each other. The departures from the expected angular distributions can be used to gain information on the momentum distribution of the electrons with which the positrons annihilate. Thus positron annihilation becomes a tool to learn more concerning the internal structure of materials.

POTENTIAL

The earliest concept of potential was developed for electric phenomena by Simeon Poisson, George Green and others in the period from about 1813 to 1827. It was realized that energy could be released from electrically charged bodies, and the concept of potential was developed as one characteristic of such a charged system that measured the ability of the system to release this energy. The energy stored in the system was and is called *potential energy*, as contrasted to dynamic or kinetic energy, hence the acceptance of the term *potential*. This concept is a scalar quantity as contrasted to a vector quantity.

Although electric potential is the most usual form of potential, other forms have also been defined to serve particular needs. These include

the scalar magnetic potential and the vector magnetic potential to be discussed later.

Closely associated with the concept of electric potential was the concept of *charge* that had been formulated by Charles Augustin de Coulomb and others over about a 100-year period starting about 1737. The electric scalar potential of a macroscopic system is defined as the electric energy of the system divided by the electric charge. This simple definition presumes a basic two-conductor, statically charged system. The mathematical expression for the definition of the potential Φ is

$$\Phi = \frac{W}{Q}$$

where W is the energy of the system and Q is the charge (see list of units at end of article).

Modern electric systems employ the concept of potential for much more sophisticated forms through the use of summations of charge effects either in discrete or in distributed forms. The complete expression for electric potential caused by the accumulation of a number of concentrated charges Q_k , surface charge density σ over a surface S , and volume charge density ρ in a volume V , all being located in a dielectric media of uniform permittivity ϵ , is

$$\Phi = \sum_{k=1}^n \frac{Q_k}{4\pi\epsilon r} + \frac{1}{4\pi\epsilon} \int_S \frac{\sigma ds}{r} + \frac{1}{4\pi\epsilon} \int_V \frac{\rho dv}{r}$$

where r measures the magnitude of the distance from the point at which the electric potential is evaluated to each charged particle or element of charge.

The difference in electric potential from one point a to another point b in a static electric field is related to a vector function called the electric field intensity \mathcal{E} (a characteristic of the space related to the negative of the gradient of the electric potential) through the line integral relationship

$$\Phi_{ab} = - \int_a^b \mathcal{E} \cdot d\mathbf{l},$$

where \mathbf{l} is a vector direction measured along the path in the direction from the point a to the point b , and the scalar product between \mathcal{E} and $d\mathbf{l}$ is denoted by the dot or scalar product notation.

The inverse form of this integral expression is the gradient form for the static electric field intensity, namely

$$\mathcal{E} = - \nabla \Phi$$

where the ∇ symbol is a vector differential space operator which, when applied to the scalar electric potential Φ , yields the electric potential gradient.

An extension of spatial derivative operations yields another function of the scalar electric potential Φ , known as the scalar Laplacian, as $\nabla^2 \Phi$. This term, when equated to the negative of the volume space charge density ρ divided by the permittivity of the space, is known as Poisson's equation. Thus,

$$\nabla^2 \Phi = -\rho/\epsilon$$

If the electric volume charge density is zero, the above relationship becomes

$$\nabla^2 \Phi = 0$$

and is known as Laplace's equation.

Electric charges in motion produce magnetic effects, which result in a magnetic field intensity vector \mathbf{H} , somewhat analogous to the corresponding vector \mathcal{E} in electric field phenomena. The line integral relationship between this vector \mathbf{H} and the vector direction measured along a path in space from point a to b establishes an analogous scalar magnetic potential Ψ_{ab} as

$$\Psi_{ab} = - \int_a^b \mathbf{H} \cdot d\mathbf{l}$$

This function is useful in the evaluation of magnetic field geometric relations for locations in space where the electric current density is zero.

For regions in magnetic fields where current densities exist, a designation of a magnetic potential relation can only be made through a function called the *vector magnetic potential*. This vector is defined in a form similar to the expression for scalar electric potential caused by a volume distribution of electric charge density as given earlier. Thus, the vector magnetic potential \mathbf{A} at a point in space caused by a distribution of current density \mathbf{J} over a volume V is

$$\mathbf{A} = \frac{\mu}{4\pi} \int_V \frac{\mathbf{J} dv}{r}$$

where μ is the permeability of space and r is the magnitude of the distance from the point at which \mathbf{A} is evaluated to each element of current density of the system. The point under consideration can be a point within the region of current density.

The vector magnetic flux density \mathbf{B} in such a space is related to the vector magnetic potential \mathbf{A} through a spatial differential function called the curl and symbolized by the operational form as

$$\mathbf{B} = \nabla \times \mathbf{A}$$

An extension of spatial derivative operations upon the vector magnetic potential also yields another function of this potential known as the vector Laplacian, $\nabla^2 \mathbf{A}$. This term is related to the current density \mathbf{J} at a point in the field as

$$\nabla^2 \mathbf{A} = -\mu \mathbf{J}$$

This expression is analogous to the similar scalar Laplacian of the electric potential which was related to the electric charge density at the point of evaluation.

For systems in which the charges are moving in such a manner that the vector magnetic potential is not constant with respect to time, the elementary form of the relationship between the electric field intensity \mathcal{E} and the scalar electric potential Φ must be modified to include a

function of the vector magnetic potential, namely

$$-\nabla \Phi - \frac{\partial \mathbf{A}}{\partial t}$$

This is the general expression that is valid at a point in space for all conditions. As action at a distance is considered, the elementary forms for the evaluation of the scalar electric potential Φ and of the vector magnetic potential \mathbf{A} , however, must recognize the time delay in action with respect to the causes.

If the scalar electric potential at a point P is to be evaluated at some time t , the *retarded potential* must consider the finite velocity of propagation that occurs in the path length r between the point P and the location of the charge that causes the electric potential.

Depending upon the nature of the charge, the retarded potential expression can be expressed in terms of the retarded time $t - r/c$, where c is the velocity of the propagated effect in free space. For the case in which the charge is distributed over a volume, the expression becomes

$$\Phi_{P,t} = \frac{1}{4\pi\epsilon} \int_V \frac{[\rho]_{t-r/c} dv}{r}$$

The symbol $[\rho]_{t-r/c}$ indicates that the charge density at the source of the field is that evaluated at an earlier time $t - r/c$. If the charges are discrete or distributed over surfaces, the corresponding forms of the potential function for these geometries would be used.

In a similar manner, the retarded vector magnetic potential can be expressed for a volume distribution of current density as

$$\mathbf{A}_{P,t} = \frac{\mu}{4\pi} \int_V \frac{[\mathbf{J}]_{t-r/c} dv}{r}$$

All preceding relations are expressed in a form that results if a rationalized system of units is used. The internationally accepted units that conform with that preceding relationships are:

Entity	Symbol	Unit
Energy	W	joule
Potential (electric)	Φ	volt
Charge	Q	coulomb
Length	r, l	meter
Area	S	meter ²
Volume	V	meter ³
Surface charge density	σ	coulomb/meter ²
Volume charge density	ρ	coulomb/meter ³
Permittivity	ϵ	farad/meter
Electric field intensity	\mathcal{E}	volt/meter
Magnetic field intensity	\mathbf{H}	ampere/meter
Scalar magnetic potential	Ψ	ampere
Vector magnetic potential	\mathbf{A}	weber/meter
Permeability	μ	weber/meter-ampere
Magnetic flux density	\mathbf{B}	tesla
Current density	\mathbf{J}	ampere/meter ²
Time	t	second
Velocity	c	meter/second

POWER. See WORK POWER AND ENERGY

PRESSURE. See FLUID STATICS

PRESSURE, VERY HIGH

For the purposes of this article "very high pressure" is defined as the range above 50 kilobars. Discussion is confined to apparatus and experiments capable of performance in this range. Thus, no discussion of the vast array of sophisticated measurements in the 12 to 20 kilobar range is included.

The increasing interest in research at very high pressure has been stimulated in part by the synthesis of diamond at General Electric, in part by an expansion of experimental GEOPHYSICS, and in large part by an increased appreciation of the importance of relatively large variations of interatomic distance in our understanding of the electronic structure of solids.

It is convenient to divide the available types of equipment into those capable of chemical synthesis on a reasonable scale and those primarily useful for physical measurements.

Among the former group, the most straightforward is the piston and cylinder device brought to its highest development by Kennedy and his colleagues at UCLA. With appropriate support it is capable of 70 kilobars. In this apparatus the pressure determination is more direct and probably more accurate than in the others.

The most generally useful apparatus for relatively large scale work at higher pressures is the General Electric "belt." As originally designed by Hall, pressures of perhaps 140 kilobars were possible. Later modifications by Bundy have extended this range by another 40 to 50 kilobars. The essential feature of the device is support for the pistons which increases with increasing pressure.

A third "large volume" apparatus in general use is the tetrahedral press first developed by Hall and modified by Hutton. In its smaller scale versions it appears capable of 100 kilobars or more, but the larger scale-ups are somewhat more limited.

All three of the above types of equipment can be operated at elevated temperatures, to 1000°C or beyond, although the accuracy of both pressure and temperature measurements is limited under these extreme conditions.

By far the most common "small scale" equipment used for physical measurements at high pressure is the tapered anvil design originated by P. W. Bridgman. It has the great advantage of relative cheapness of construction and ease of loading. While pressure gradients are a problem, they have not limited its broad application. Originally developed for electrical resistance measurements, it has since been applied to x-ray scattering, to Mössbauer studies, and (with diamond anvils) to optical absorption studies. While there have been a number of estimates of the pressure range of Bridgman anvils, the probable upper limit is near 150 kilobars.

A modification of the tapered anvil apparatus has given the highest pressures yet obtained statically. This involves very small flats, work hardened, sintered, tungsten carbide pistons, and support on the taper which increases with increasing pressure, so that the net effect is that measurements are made in a cell surrounded by rings of material at continuously decreasing pressure. With modifications of this apparatus, optical absorption measurements have been made to 160 to 170 kilobars, electrical resistance and x-ray diffraction studies to over 500 kilobars, and Mössbauer studies to beyond 250 kilobars. The apparatus has been operated from 77 to 650°K, but increasing temperature above 300 K limits the pressure range rapidly.

Finally, mention should be made of shock velocity measurements. With this technique p - v measurements have been made at pressures of 2000 kilobars both at Los Alamos and by Russian workers. Measurements have largely been confined to p - v relations to date, but other types are apparently possible. The correction from adiabatic experiments to isothermal data limits the accuracy for very compressible materials.

The problem of calibration is a complex one, and only an outline can be given here. The most usual method has been to observe discontinuities in electrical resistance due to first-order phase changes in certain metals. A serious problem is that these materials exhibit varying degrees of metastability which are not independent of the apparatus. The calibration problem at elevated or reduced temperature is still more serious. Points most frequently used at 300°K are transitions in bismuth at 25 and 87 kilobars, in thallium at 37 kilobars, in barium at 59 and 140 kilobars, in iron at 130 kilobars, and in lead at approximately 160 kilobars. Beyond this point, the difficulties increase. By means of x-ray measurements on systems where shock wave data are available, consistency between shock and static measurements has been established to over 500 kilobars. Internal consistency among some shock measurements has also been shown by x-rays on mixed powders. One certain conclusion is that extensive extrapolation of linear calibrations established at low pressure invariably predicts pressures much higher than are obtainable.

In a brief article such as this it would be impractical to review in any detail the experimental results, but an outline of major features is feasible.

A great deal of careful effort has gone into the establishment of melting curves and phase boundaries between two solid phases. Items of particular interest in the first category include maxima in the melting points of cesium and barium discussed by Kennedy and co-workers. High pressure phase transitions to a metallic state have been discovered in silicon, germanium, gallium arsenide, gallium antimonide, aluminum antimonide, indium arsenide, indium phosphide, indium antimonide, zinc sulfide, zinc selenide, zinc telluride, and other III-V and III-IV compounds. Recent x-ray studies indicate that the high pressure phases of silicon and germanium have the white tin structure while a number of the III-V compounds have a closely related atomic arrangement. On the other hand, ZnSe and ZnTe appear to adopt the face-centered-cubic NaCl structure at high pressure. In the case of InSb and a few related compounds it has been possible to quench in the high pressure phase at one atmosphere and to show that these are indeed SUPERCONDUCTORS below about 3°K. (See CRYSTALS AND CRYSTALLOGRAPHY and SEMICONDUCTIVITY.)

The General Electric group have shown that after compression into the metallic phase and release of pressure, silicon and germanium retain rather a complex cubic or tetragonal arrangement which is neither white tin nor diamond. It has not yet been shown whether these intermediate phases have any definite range of true stability. Moderate heating at one atmosphere suffices to return these materials to the diamond structure.

The pressure-volume measurements by Swenson and his co-workers at Iowa State on alkali metals and solidified rare gases at liquid helium temperature have given an important impetus to our understanding of interatomic forces in relatively simple systems.

Shock wave studies have provided p - v data on nineteen metals to 2000 kilobars and a number of others to 500 kilobars, as well as compressibilities of a number of alkali halides to the 300 to 400 kilobar region.

X-ray measurements have shown that the high pressure phase of iron is hexagonal close packed with a very anisotropic compressibility (c/a is 1.64 at 150 kilobars and 1.58 at 400 kilobars). Recent measurements on lattice parameters of magnesium reveal a rather complex behavior for the c/a ratio which can be related to interaction between the Fermi surface and the Brillouin zone boundaries.

A very interesting high pressure phenomenon is the electronic transition. Cesium exhibits a cusp in the resistance at 41 kilobars and a second maximum above 200 kilobars. Rubidium has a distinct maximum in its resistance above 400 kilobars, while potassium shows a very sharp rise in resistance (by a factor over 50) in 600 kilobars. These phenomena have been associated with the promotion of an s electron to the empty d shell which is at higher energy in the free atom and the low pressure solid. The increase

in pressure at which this takes place going from cesium to potassium can be associated with the greater energy difference between $3d-4s$ as compared with $4d-5s$ and $5d-6s$ shells.

Cerium has a transition at five kilobars which is associated with $5d-4f$ electronic mixing, and many of the RARE EARTH metals exhibit unusual resistance behavior at high pressure which can almost certainly be related to mixing between $4d$, $5f$, and other nearby levels. Strontium and calcium among the alkaline earth metals exhibit transitions to a semiconducting or semimetallic state at high pressure and then ultimately become metallic again.

In insulators and SEMICONDUCTORS, one of the more significant studies involves the shift of the optical absorption edge (gap between the conduction and valence band) with pressure and the accompanying change in electrical resistance. A number of features concerning the band structure of silicon, germanium, and related compounds have been revealed by these measurements.

The continuous approach to the metallic state is best illustrated by studies on iodine where a very close agreement is shown between the activation energy for electrical conduction and half the optical energy gap. Between 160 to 240 kilobars the resistance is metallic in one direction but not in the other, much like graphite. At higher pressures the behavior is distinctly metallic.

High pressure optical studies on the alkali halides have been important in elucidating the electronic structure in the neighborhood of imperfections. The local compressibility of the F center is about twice the bulk compressibility at low pressure and decreases to perhaps 1.2 to 1.4 times the bulk compressibility above 100 kilobars. This is quite consistent with the picture of a vacancy containing a trapped electron.

A well-known phosphor involves a thallous ion as a substitutional impurity in an alkali halide lattice. The pressure dependence of the optical absorption due to this impurity shows that the transition involved is closely bound to the thallous ion in the halides, but is more spread out in the iodides.

Crystal field theory has been a very important first-order picture of the ENERGY LEVELS of transition metal ions in crystals and complexes. The effect of pressure on the transition energy shows very clearly the applicability and limitations of the theory. In rigid ionic networks such as Al_2O_3 , the energy increases as the inverse fifth power of the interatomic distance, as required by simple crystal field theory. In most cases, however, it is clear that the point "charge" assumption of crystal field theory is inadequate for quantitative calculations, and increasing pressure results in spreading out of the electron cloud and decreased interelectronic repulsion among the $3d$ electrons.

It is not hard to see that there is scarcely an area of solid-state physics where high pressure measurements are not capable of providing a significant test of theory.

A number of good references are available. Bridgman's¹ monograph remains a classic. The book edited by Wentorf² and Swenson's³ review paper give excellent discussions of techniques as of 1961, although much has developed since. Recent books edited by Warshauer and Paul⁴ and by Bradley⁵ cover many applications. The former is of especial interest to solid state physicists. A paper in *Advances in Chemical Physics*⁶ reviews some studies on electronic structure.

PROPAGATION OF ELECTROMAGNETIC WAVES

The discussion of propagation phenomena in general media requires a rather elaborate and sophisticated mathematical formalism. For a detailed treatment of those disturbances that fall into a category of wave phenomena, an ELECTROMAGNETIC THEORY of characteristics whose origin lies in the subject of partial differential equations has long been available.

Two viewpoints are of interest for an understanding of the mechanism of propagation of an electromagnetic wave: the macroscopic phenomenological theory of Maxwell and the microscopic theory of Lorentz. The Maxwell theory avoids the explanation of what happens to the individual charged particles that constitute the medium in which the phenomena are taking place; the influence of the medium is accounted for by means of factors called constitutive parameters. The effect of the electric field of equal numbers of oppositely charged particles that make up the medium is accounted for by the permittivity ϵ . The effects of the motions of the charges comprising the medium on the fields are taken into account in the following manner: the motion of the unbound charges is subsumed under the conduction current by means of a conductivity σ ; the translational motion of the bound charges is subsumed in the electric-displacement field by means of the permittivity ϵ ; and the rotational motion of the constituent charges is subsumed in the magnetic-induction field by means of the permeability μ .

This representation of the dynamical behavior of the constituent charges by means of the parameters ϵ , μ , and σ has proved to be of great

practical importance, since one can separate the study of the macroscopic behavior of the fields from that of the macroscopic behavior of the constituents of the medium in which the fields are present. In many media these constitutive parameters can be determined by empirical means much more easily than by theoretical considerations. For such media the macroscopic theory is clearly most suitable.

In an ionized gas (in contrast to media made up of neutral molecules), it is difficult to measure the constitutive parameters. The difficulty arises from the fact that the space charges present and the boundary condition imposed by the measuring apparatus affect each other significantly. To determine these parameters a knowledge of the dynamical behavior of the microscopic constituents is required, which leads us to the second point of view, the exhaustive microscopic theory of Lorentz. This theory attempts to describe all electrical phenomena in terms of the elementary positive and negative charges comprising the medium. The theory dispenses with the concept of the material medium and considers only the ensemble of negative and positive charges (which actually constitute the medium) in free space. More specifically, the theory postulates that in all permeable bodies there exists a large number of charged particles of very small size, which are separated from each other by free space. Conducting bodies are imagined to be constituted of a large number of free particles capable of being moved through the body under the action of an electric force. Nonconducting or weakly conducting bodies are considered to be made up of particles bound to their positions of equilibrium by an elastic force. Even though they are displaced from their equilibrium positions, this displacement is not very large (small oscillations). It is also postulated that the medium has no net charge, so that the positive and negative charges balance exactly. When particles are displaced from their equilibrium positions, the medium becomes polarized.

The Lorentz theory further assumes that the free-space displacement current exists not only in the empty space between the particles but also within the particles themselves. The action of the material medium participates in this theory if we consider the motions of the charged particles under the influence of the electromagnetic forces as a fundamental concept. If each particle has a charge q and a mass m , then under the action of the electric force the particle is displaced from its equilibrium position, and at time t has a velocity of magnitude v . However, the moving charge produces a current qv , and if there are N such particles per unit volume, they give rise to a convection current density Nqv (by v we understand the time-average value of the charge velocity). The average convection current density can be written as $Nqv = \rho v = J$ regardless of whether the charges are free or bound.

For varying fields, it is not clear *a priori* whether this total current is a conduction current proportional to the electric intensity and in

phase with it, or a displacement current proportional to $\dot{\mathbf{E}}$ and out of phase with the electric intensity \mathbf{E} by $\pi/2$. Consequently, the total current density must be written as the sum of the free-space displacement current and the material convection current.

Let us summarize the two views: the Maxwell theory describes the phenomena in terms of the equations

$$\nabla \times \mathbf{E} + \dot{\mathbf{B}} = 0 \quad (1)$$

$$\nabla \times \mathbf{H} = \mathbf{J} + \dot{\mathbf{D}} \quad (2)$$

$$\nabla \cdot \mathbf{D} = \rho \quad (3)$$

$$\nabla \cdot \mathbf{B} = 0 \quad (4)$$

supplemented by the relations

$$\mathbf{B} = \mu \mathbf{H} \quad (5)$$

$$\mathbf{D} = \epsilon \mathbf{E} \quad (6)$$

$$\mathbf{J} = \sigma \mathbf{E} \quad (7)$$

The Lorentz microscopic theory describes the electromagnetic phenomena by the same set of Maxwell's equations as given above, but since there is no medium in this point of view, the relations (eqs. 5, 6 and 7) must be given in vacuo,

$$\mu = \mu_0 \quad \epsilon = \epsilon_0 \quad (8)$$

and the current density is given directly in terms of the moving charges:

$$\mathbf{J} = \sum_k q_k \mathbf{v}_k / \text{volume of region containing charges} \quad (9)$$

Maxwell's equations relate the fields to the charges and their motions, but since these motions are not known, it is necessary to supplement them with the dynamical equations of motion for the charges. These equations have the form, for each particle q_k ,

$$\frac{d(m_k \mathbf{v}_k)}{dt} = q_k (\mathbf{E} + \mathbf{v}_k \times \mathbf{B}) \quad (10)$$

where \mathbf{B} is the *total* magnetic induction field evaluated at the position \mathbf{r}_k of the k th particle and \mathbf{E} is the *total* electric field evaluated at \mathbf{r}_k . These fields can consist in part of external fields and in part of fields due to the q_k 's themselves.

Equations (1) through (10) must be solved simultaneously for the dynamical behavior of the charges, and from this behavior we can derive the constitutive parameters for the macroscopic model of the medium.

In the Lorentz theory, the motion of the electrical charges is described in terms of the polarization vector (dipole moment per unit volume) rather than in terms of the convection current. In this case the polarization vector $\mathbf{P} = Nq\mathbf{r}$, \mathbf{r} being the average displacement of the charged particles. Consequently, $\mathbf{J} = \dot{\mathbf{P}}$.

In order to discuss propagation in PLASMAS, the relationship between the polarizations (or

the current density) and the electric intensity must be added to Maxwell's equations; this completed set we call the Maxwell-Lorentz equations.

In the ionized gas, the electrons and ions are detached completely from their parent molecules; no elastic forces bind them as in the case of a solid body such as a crystal; the particles have no free period of oscillation of their own. But under the influence of an applied force, they are disturbed by collisions with the neutral molecules. In the collision process some of the energy of motion of the electrons and ions is converted into energy of random motion of particles, i.e., heat energy. The charged particles are therefore losing energy continually, and this loss can be represented as a resistance to their motions. This simple model of a resistive mechanism is incorporated into the equations of motion of the charged particles as a damping force.

The electron theory of Lorentz gives some idea of the mechanism by which the charged particles alter the phase velocity of a propagating electromagnetic wave field. Consider a semi-infinite medium separated by a plane interface from the free space, and imagine an electromagnetic wave field propagating in free space impinging upon the medium. The electromagnetic wave traveling through the free space between the particles excites the charged particles and causes them to oscillate so that they essentially become small dipole oscillators, the wave field governing their phase of oscillation.

At each point either in or external to the region in which the particles are contained, the secondary waves radiated by the oscillators interfere with the original wave field and with the other radiated waves; the sum of all the waves is a resultant field at the point. Moreover, it is the resultant field that acts on the particles at the given point which causes them to vibrate. The total intensity at any point is the vector sum of the intensity of the original wave field and the resultant intensity due to all the oscillating particles. According to this picture, in general, the emerging wave has its phase velocity altered. Reflective waves are treated in a similar manner.

Plane Wave Fields: Dispersion Relations. Consider the kind of waves that an unbounded homogeneous medium can support, in the presence of a uniform (in space-time) externally applied magnetic field. Although this is not the most general situation, a great many of the salient features may be culled from it. The Maxwell-Lorentz equations, together with the postulated magnetic field, permit us to examine the existence of simple plane wave fields, i.e., field quantities proportional to $\exp(-j\mathbf{k} \cdot \mathbf{r})$ where \mathbf{k} is the wave vector whose components are in general, complex. For fields with harmonic time dependence, the above assumptions lead to the condition for propagation which takes the form

$$\Delta(\mathbf{n}, \omega, \dots) \mathbf{E} = 0 \quad (11)$$

The condition for propagation is thus seen to

reduce to the question of the existence of non-trivial fields, i.e., $\mathbf{E} \neq 0$. The necessary and sufficient condition for this is simply the vanishing of the determinant

$$\Delta(\mathbf{n}, \omega, \dots) = 0 \quad (12)$$

which expresses an algebraic relation between the wave normal direction \mathbf{n} (defined through $\mathbf{k} = k\mathbf{n}$, k a complex scalar) and the impressed frequency ω of the wave field. The other factors not specifically indicated are functions of the parameters of the medium itself. This algebraic relation is often called a "dispersion relation," since it is a relation for ω . It is only when this condition is fulfilled that a propagating plane wave field is possible. This condition also implies an equation for the refractive index of the medium. The same considerations that led to this relation also lead to a relation between the displacement field \mathbf{D} and the electric field \mathbf{E} , in the form

$$\mathbf{D} = \epsilon_0 \epsilon' \mathbf{E} \quad (13)$$

where ϵ' is a tensor whose structure for a particular choice of coordinate system (applied magnetic field co-directional with the x_3 -axis) is

$$\epsilon' = \begin{pmatrix} \epsilon_1 & j\epsilon_2 & 0 \\ j\epsilon_2 & \epsilon_1 & 0 \\ 0 & 0 & \epsilon_3 \end{pmatrix} \quad (14)$$

Here, the ϵ_j ($j = 1, 2, 3$) are complex valued and are functions of the parameters of the medium. If the medium is magneto-ionic (ions, electrons, and neutral molecules) and if collisions take place only between the charged species and the neutrals comprising the medium, the ϵ_j 's are rational functions of the medium parameters and the dispersion relation is also called the Appleton-Hartree equation, both of whom derived the relation independently.

The fact that the dispersion relation of such a medium depends upon the direction of the wave normal direction and ω makes the fourth-degree algebraic equation defining the refractive index complicated in practice. Theoretically, two indices are defined; the medium is doubly refracting in this case, analogous but certainly not identical with propagation in certain crystals, and this plasma crystal optics analogy can be advantageously exploited.* The propagating wave fields associated with each index are called, respectively, the *ordinary* mode, because it is least effected by the applied magnetic field, and the *extraordinary* mode. These two modes are linearly independent i.e., one of them cannot be expressed as a simple multiple of the remaining one. Both modes, in passing through the medium undergo attenuation and rotation of their respective planes of polarization; the so-called FARADAY EFFECT is present here as in some crystals. This effect is used in electron-density determinations, since the density

can be expressed in terms of the angle of rotation of these planes. The planes of polarization of each mode rotate opposite to each other.

Two important parameters (characteristic frequencies) are involved in discussing propagation: (1) the *plasma* frequencies of the constituents ω_j , defined by

$$\sqrt{N_j e^2 / \epsilon_0 m_j},$$

where subscript j stands for the type of species (electron, ion, etc.), N_j is the number density, m_j its mass, and e the electronic charge; and (2) the gyro or *Larmor* frequency defined by $\Omega_j = B_0 e / m_j$, where B_0 is the magnitude of the applied magnetic field and ω is the impressed wave frequency. The plasma frequency is essentially a resonant frequency and is more closely tied to the concept of collective motion or plasma oscillations. The Larmor frequency is a well-known concept and is substantially the frequency with which a charged particle "winds" itself about the externally applied magnetic field in the absence of collisions. If $\omega \neq \omega_j$ for all j , propagation is possible; if the medium consists only of electrons, the above condition is well known in ionospheric radio wave propagation.

Plasma Waves. For a more complicated description of the medium, other modes of propagation are possible. If the Lorentz force equation is extended so as to include pressure gradients (temperature effects are naturally included in the description by simple use of the gas laws), a hydrodynamic model of the gas results; and since this model is coupled to the electrodynamic equations through the Lorentz force term, we speak of magnetohydrodynamics or (to be more inclusive) magneto-fluid dynamics and its various synonyms (see MAGNETO-FLUID-MECHANICS). To see the effect of this coupling, we should recall that a completely incompressible perfect fluid with no magnetic field imposed cannot support any wave-like disturbances, as is obvious on physical grounds. This result is also clear on mathematical grounds in which the velocity potential satisfies Laplace's equation whose solutions are certainly not wave-like. If now the fluid is still incompressible but conducting and with a magnetic field imposed upon it, wave phenomena are now possible; the resulting waves are called magnetohydrodynamic and include both longitudinal and transverse types.

In the high-frequency limit, these waves yield the usual radio waves mentioned above; in the low-frequency limit, the resultant waves are no different in principle. However, because of the coupling of the more extensive hydrodynamic model with the electrodynamic field equations, the intermediate frequency region is naturally more complicated. The conditions for propagation (i.e., the dispersion relations) can no longer be readily discussed in general. The coupling, on the other hand, opens up a vast new area of investigation of wave phenomena, the existence of plasma waves, which was investigated initially by the astrophysicist Alfvén. In the case of an unbounded homogeneous medium, it is possible

* See, for instance, J. Brandstatter, "An Introduction to waves, Rays and Radiation in Plasma Media", New York, McGraw-Hill Book Co. (1963)

to treat, in a systematic way, the propagation of plane wave fields.

The conclusions drawn from the extensive hydrodynamical model in the low-frequency limit are also obtainable from a simpler point of view. For a magneto-ionic medium and $\omega \ll \omega_p$, Astrom and others deduced the properties of plane wave propagation by elementary considerations and arrived at the same result as Alfvén. The energy associated with the extraordinary mode proves to be propagated along the magnetic field lines. This manner of propagation sheds light on whistlers, a low-frequency natural phenomenon that exhibits similar properties. It is also worthwhile noting that since the dielectric tensor is in general non-symmetric, the condition of reciprocity (interchange of transmitter and receiver) does not hold as in the isotropic case in which ϵ reduces to a single scalar quantity. Finally, in the homogeneous unbounded case, the mean Poynting vector is *not* co-directional with the wave normal direction of either mode.

Nonhomogeneous Media. In nonhomogeneous, nonmagnetic media whose dielectric tensor varies in only one direction, the problem of calculating the wave fields can be reduced to the calculation of a Hertzian vector potential function, which satisfies an integral-equation relation. Here, one can employ variational techniques similar to those used by Schwinger, Levine, and others to find approximate solutions. Numerical techniques based on matrix theory have likewise been exploited. General reflection and transmission matrices are by-products of this problem. Other attempts to deal with this kind of problem, particularly for a doubly refracting medium separated from free space by a horizontal plane, are based on the ideas of Booker *et al.* A plane wave penetrating the medium from free space below splits into an ordinary and extraordinary wave. Because of the inhomogeneity of the medium, the penetrating waves which start at the plane interface generate along their path two ascending and two descending waves, the latter because of postulated internal reflections. The four waves so produced have different wave normal and Poynting vector directions. Snell's law is valid for both the ordinary and extraordinary waves. The inhomogeneous character of the medium causes the four waves, each of different elliptical polarization, to be coupled to each other. K. Suchy has shown that in the general nonhomogeneous medium, with no assumptions of stratification, Maxwell's equations reduce to a pair of coupled equations which has its simplest structure for a certain class of curvilinear coordinates. He has also treated the propagation of electromagnetic waves in absorbing, anisotropic, inhomogeneous, and unbounded media and studied in some detail the transition from the full vector wave equation with arbitrary wavelength λ to small values of λ but nonvanishing.

Ray-theoretic Approach. The study of propagation in anisotropic, inhomogeneous media becomes amenable to analysis by means of a

ray theory. Under the assumption that the wavelength λ is very much smaller than some characteristic dimension of the medium, it becomes possible to replace the more complicated vector field equations defined through the Maxwell-Lorentz system by a much simpler structure. By analogy with the homogeneous case, \mathbf{E} is taken to be proportional to

$$A(\mathbf{r}) \exp \left[j \left(\omega t - \omega \int \mathbf{M} \cdot d\mathbf{r} \right) \right]$$

where \mathbf{M} is in general a complex-valued vector. The \mathbf{H} field is expressed similarly. If this expression is used in the vector wave equation for \mathbf{E} we are led to a system with the following structure:

$$(\mathbf{L} - \epsilon)\mathbf{E} = 0 \quad (15)$$

where \mathbf{L} is a matrix whose elements contain the differential operators $\partial^2/\partial x_i \partial x_j$, and are complex. The condition for propagation is still the vanishing of the determinant $|\mathbf{L} - \epsilon|$, which is now a nonlinear partial differential equation of the second order for the three components of \mathbf{M} . The matrix \mathbf{L} is known as the "Eikonal matrix," and the above dispersion equation constitutes a generalization of the usual Eikonal equation or equation of geometrical optics. To understand the significance of the Eikonal equation, we consider a scalar wave equation whose spatial dependence f is of the form,

$$\nabla^2 f + \left(\frac{\omega M}{c} \right)^2 f = 0 \quad (16)$$

By taking $f(\mathbf{r}) = A(\mathbf{r}) \exp [- 2\pi j \psi(\mathbf{r})]$ and setting both the real and imaginary parts to zero, we obtain two nonlinear partial differential equations for the determination of both A and ψ . If both of these functions vary slowly within a distance of a wavelength, these equations simplify and one can find ψ without having to also find A . The resulting expression under these conditions for ψ is the Eikonal equation

$$4\pi^2 (\nabla \psi)^2 = \left(\frac{\omega M}{c} \right)^2 \quad (17)$$

whereas that for A takes the form

$$\nabla \cdot (A^2 \nabla \psi) = 0 \quad (18)$$

We can now easily relate ψ to \mathbf{M} ; indeed we put

$$\psi = \psi_1 - j\psi_2, \quad \mathbf{M} = \boldsymbol{\mu} - j\boldsymbol{\chi} \quad (19)$$

and in general both ψ and \mathbf{M} are functions also of frequency. The complex phase ψ is defined through

$$\psi = \int_{\mathbf{r}_0}^{\mathbf{r}} \nabla \psi \cdot d\mathbf{r} = \frac{\nu}{c} \int_{\mathbf{r}_0}^{\mathbf{r}} \mathbf{M} \cdot d\mathbf{r} \quad (20)$$

where $d\mathbf{r}$ is a real vector and ν the frequency. The vector $\boldsymbol{\mu}$ is normal to the family of surfaces $\psi_1 = \text{constant}$, and $\boldsymbol{\chi}$ is normal to the family

$\psi_2 = \text{constant}$; these surfaces are in general distinct, and therefore we put

$$2\pi\psi_1 = \frac{\omega}{c} \int_{p_0}^p \mu \cdot d\mathbf{r} \quad (21)$$

$$2\pi\psi_2 = \frac{\omega}{c} \int_{p_0}^p \chi \cdot d\mathbf{r} \quad (22)$$

To find expressions for the magnitude of μ and χ we have

$$M^2 = (\mu - j\chi) = P - jQ \quad (23)$$

which is equivalent to

$$\mu^2 - \chi^2 = P; \quad 2\mu\chi \cos \theta = Q \quad (24)$$

where θ is the angle between μ and χ . These two relations yield

$$\begin{aligned} \mu^2 &= \frac{1}{2} \{ [P^2 + (Q/\cos \theta)^2]^{1/2} + P \} \\ \chi^2 &= \frac{1}{2} \{ [P^2 + (Q/\cos \theta)^2]^{1/2} - P \} \end{aligned} \quad (25)$$

the first expression defines a refractive index surface, and the second, an extinction index surface.

The equation defining A suggests a conservation law (equation of continuity) as applied to a fictitious fluid. By analogy we consider $A^2 \nabla \psi$ proportional to the current density of this fluid, and an application of the divergence theorem gives

$$\oint_V \nabla \cdot (A^2 \nabla \psi) dV = \oint_S A^2 \nabla \psi \cdot \mathbf{n} dS \quad (26)$$

where V is some volume containing the fluid and bounded by a surface S with outward drawn normal \mathbf{n} . If we consider this fluid to have (material) density proportional to A^2 and velocity proportional to $\text{grad } \psi$, then the above expression states that A^2 is conserved in time. If we assume that $|A|^2$ is a measure of the energy localized in the wave at each point, that $\text{grad } \psi$ is proportional to the energy flux at each point and is directed along the ray associated with the wave, then it appears as if the energy is a fluid which is conserved as it flows along the rays. Thus, the rays appear as trajectories of energy, a thin pencil of rays being analogous to a tube through which the energy flows.

In a homogeneous, anisotropic, but non-absorbing medium the concept of ray is defined as the trajectory whose direction is the same as that of the mean Poynting vector. This direction, as mentioned previously, is not the same as the wave normal direction. The task of defining the ray direction becomes more difficult for a non-homogeneous, anisotropic, absorbing, and dispersive medium. It can be shown that starting with the concept of a pulse in such a medium, one can derive extensions or generalizations of the usual Fermat's principle. This principle states that in a nonabsorbing, isotropic medium characterized by an index μ_r , a function of position only, the path of a so-called light ray makes the integral of μ_r between two fixed points

assume a stationary value. The pulse concept for the general case leads to the following stationary principles:

$$\begin{aligned} \delta \int \mu_r \cdot d\mathbf{r} &= 0 \\ \delta \int \chi \cdot d\mathbf{r} &= 0 \end{aligned} \quad (27)$$

$$\delta \int \frac{\partial}{\partial \omega} (\omega \mu) \cdot d\mathbf{r} = 0$$

where δ is the symbol of variation. In the non-absorbing case the first of Eqs. (27) gives the phase path, which is always normal to the surfaces of constant phase. Similarly, the trajectory of the amplitude surfaces is also normal to the surfaces of constant amplitude. For the absorbing case we retain these two definitions. This means that μ_r is always tangent to a path element of the phase trajectory and χ is tangent to a path element of the amplitude trajectory. These path elements are denoted, respectively, by $d\mathbf{r}_p$ and $d\mathbf{r}_a$. The pulse principle permits us to define, in addition to the above surfaces, the surfaces of constant group amplitude. These surfaces are distinguished from those of constant wave amplitude and constant wave phase. If $d\mathbf{r}_g$ denotes an element of the path along which the group amplitude propagates, then the stationary principle for this path takes the form

$$\delta \int \mu_r \cdot d\mathbf{r}_g = \delta \int \frac{\partial}{\partial \omega} (\omega \mu_r) \cdot d\mathbf{r}_g = 0 \quad (28)$$

and in general the direction of the vector $\partial/\partial \omega (\omega \mu_r)$ is not parallel to $d\mathbf{r}_g$. The vector $\partial/\partial \omega (\omega \mu_r)$ is the basis for the definition of the group velocity. By definition, the displacement of the center of the wave group in a time dt is

$$\mathbf{v}_g dt = d\mathbf{r}_g \quad (29)$$

where \mathbf{v}_g is the group velocity. If we define a vector $(\mathbf{v}_g)^{-1}$ (symbolic meaning only), such that

$$\mathbf{v}_g \cdot (\mathbf{v}_g)^{-1} = 1 \quad (30)$$

it is not difficult to show that

$$(\mathbf{v}_g)^{-1} = \frac{1}{c} \frac{\partial}{\partial \omega} (\omega \mu_r) \quad (31)$$

We take the path of energy propagation to be the path of group amplitude. This condition is certainly plausible when we consider that the energy of a field is usually proportional to the square of the amplitude of its oscillations.

In the case of an electromagnetic field, it is not so clear that the group path is also the energy path if this energy is measured by the mean Poynting vector, and the conditions under which this holds require careful analysis.

The question naturally arises as to how one actually calculates a ray path in the general case. The answer has been available for a long time. Hamilton's work in optics actually provides a

modus operandi for the practical calculation of the ray paths. Fermat's principle provides the starting point; we assume that the medium is characterized by an index function $m(\mathbf{r}, \alpha, \omega)$ called the ray refractive index. This function depends on position \mathbf{r} , direction α , and frequency ω , and is a homogeneous function of the first degree in α . The rays are defined as those curves such that

$$\delta \int_{r_0}^r m ds = 0 \quad (32)$$

where s is the parameter of arc length. The anisotropy is defined through the direction α which is normalized so that

$$\alpha \cdot \alpha = \frac{dr}{ds} \cdot \frac{dr}{ds} = 1 \quad (33)$$

that is, α defines the tangent to the ray. In the isotropic case this dependence is lacking and $m(\mathbf{r})$ is invariant with respect to proper rotations. Usually we do not know $m(\mathbf{r}, \alpha, \omega)$ but rather $\mu_r(\mathbf{r}, \mathbf{n}, \omega)$ where \mathbf{n} is the wave normal direction, as in the Appleton-Hartree equation. Thus it is desirable to attempt to express the ray path through the phase refractive index μ_r . This is accomplished by constructing a Hamiltonian defined by

$$H(\mathbf{r}, \sigma, \omega) = \frac{|\sigma|}{\mu_r(\mathbf{r}, \mathbf{n}, \omega)} = 1 \quad (34)$$

which is a homogeneous function of the first degree in σ , where $\sigma = \partial m / \partial \mathbf{r}$ is a vector in the direction of \mathbf{n} . It can be shown that the rays which satisfy Fermat's principle with m as index are identical with those satisfying

$$\delta \int_{r_0}^r \sigma \cdot d\mathbf{r} = 0 \quad (35)$$

whose variations are subject to the constraint $H(\mathbf{r}, \sigma, \omega) = 1$.^{*} The latter is Hamilton's principle and is fully equivalent to Fermat's principle. It follows from Hamilton's principle that the rays satisfy Hamilton's canonical equations

$$\frac{d\mathbf{r}}{dt} = \frac{\partial H}{\partial \sigma}, \quad \frac{d\sigma}{dt} = - \frac{\partial H}{\partial \mathbf{r}} \quad (36)$$

where t is a parameter along the path. Equations (36) are six simultaneous first-order nonlinear ordinary differential equations. Subject to initial conditions these equations have a unique solution. The advantage of defining the rays in terms of the first-order system as above are many, particularly from a computational point of view. The rays can be calculated for rather general media, and no assumptions of stratification are needed. The form of Hamilton's equations can easily be found for any coordinate system by tensor methods. Finally, we mention that a systematic study of ray propagation is possible without alluding to wave concepts although the ray-wave duality is implicit.

PROTON*

Protons in Atoms. The proton is the atomic nucleus of the element hydrogen, the second most abundant element on earth. Positively charged hydrogen atoms or "protons" were identified by J. J. Thomson in a series of experiments initiated in 1906. Although the structure of the hydrogen atom was not correctly understood at that time, several properties of the proton were determined. The electric charge on the proton was found to be equal but opposite in sign to that of an electron, and the measured value for the mass was much greater than that of the electron. The currently accepted proton mass is 1836 times the electron rest mass, or $1.672 \cdot 10^{-24}$ grams.

A correct estimate of the size of the proton and an understanding of the structure of the hydrogen atom resulted from two major developments in atomic physics: the Rutherford scattering experiment (1911) and the Bohr model of the atom (1913). Rutherford showed that the nucleus is vanishingly small compared to the size of an atom. The radius of a proton is the order of 10^{-13} cm as compared with atomic radii of 10^{-8} cm. Thus, the size of a hydrogen atom is determined by the radius of the electron orbits, but the mass is essentially that of the proton.

In the Bohr model of the hydrogen atom, the proton is a massive positive point charge about which the electron moves. By placing quantum mechanical conditions upon an otherwise classical planetary motion of the electron, Bohr explained the lines observed in optical spectra as transitions between discrete quantum mechanical energy states. Except for hyperfine splitting, which is a minute decomposition of spectrum lines into a group of closely spaced lines, the proton plays a passive role in the mechanics of the hydrogen atom. It simply provides the attractive central force field for the electron.

The proton is the lightest nucleus with atomic number one. Other singly charged nuclei are the deuteron and the triton which are nearly two and three times heavier than the proton, respectively, and are the nuclei of the hydrogen isotopes deuterium (stable) and tritium (radioactive). The difference in the nuclear masses of the isotopes accounts for a part of the hyperfine structure called the "isotope shift."

In 1924, difficulties in explaining certain hyperfine structures prompted Pauli to suggest that a nucleus possesses an intrinsic angular momentum or "spin" and an associated magnetic moment. The proton spin quantum number (I) is $1/2$, and the angular momentum is given by $[I(I+1)h^2/(2\pi)^2]^{1/2}$ where h is Planck's constant.

^{*} Supported in part by The U.S. Air Force Office of Scientific Research.

The intrinsic magnetic moment is 2.793 in units of nuclear magnetons (0.50504×10^{-23} erg/gauss) which is about a factor of 660 less than the magnetic moment of the electron.

Two types of hydrogen molecule result from the two possible couplings of the proton spins. At room temperature, hydrogen gas is made up of 75 per cent orthohydrogen (proton spins parallel) and 25 per cent parahydrogen (proton spins antiparallel). Several gross properties, such as specific heat, strongly depend on the ortho or para character of the gas.

Protons in Nuclei. Protons and neutrons are regarded as "nucleons" or fundamental constituents of nuclei in most theories of nuclear structure and reactions. The nuclear forces operating between them are much stronger than the electrostatic forces which govern atomic and molecular systems but operate over very short ranges, the order of several times 10^{-13} cm. Of particular significance in the structure of nuclei is the apparent charge independence of the forces. That is, the nuclear force between two nucleons may be considered separately from the electrostatic forces due to electric charges the nucleons may carry. In addition to mass and charge, other properties such as spin and parity play important roles in determining the mechanics of nuclei.

The mass of a nucleus is the sum of the masses of the nucleons contained, plus a correction due to the total binding energy of the nucleons. This correction is an application of the Einstein mass-energy equivalence ($E = mc^2$). The atomic number or positive charge of a nucleus is given by the number of protons.

A detailed description of the motion of a proton in a nucleus is complicated by the many-body, quantum mechanical nature of the problem, but several simplified theories or models have been very successful in predicting many of the properties of nuclei. One of the best known nuclear structure models is the shell model in which a nucleon is assumed to move in a central force field. This field represents the average interaction of the proton (or neutron) with all other nucleons. An essential additional assumption is a coupling of the orbital angular momentum of the independent nucleon with its spin.

The success of a theory in which a nucleon moves among its close-packed neighbors as if they were not present is due in part to quantum mechanical restrictions, in particular to the Pauli exclusion principle.

The optical model for the scattering of protons by nuclei also rests on the assumption that the interaction with many nucleons may be represented by an average potential well. An imaginary potential term is included which accounts for reactions other than elastic scattering.

Much of nuclear physics may be understood with a picture in which the proton exists as an independent particle in the nucleus. Refinements of an independent particle model to include collective effects and deformation involve a consideration of the residual interaction between

nucleons and the details of the individual nucleon interaction with the average potential well.

Certain aspects of the very strong nuclear forces are understood. These forces involve π mesons in somewhat the same way that electrostatic forces responsible for atomic structure involve photons. Yukawa introduced the π meson as the field quantum for nuclear forces in 1935, and the interaction potential derived from this early theory is commonly used in nuclear physics.

Structure of the Proton. A major objective of physics is to identify elementary particles and determine their properties. The proton is important in these investigations in several connections. It is itself an elementary particle. It is used as a projectile in the production and study of other elementary particles. It has been used as a target in the study of nucleon structure.

One view is to consider all fundamental particles as states of excitation of a limited number of particles. The resulting simplification correlates a large body of experimental data.

The internal structure of the proton is still being studied. In one of the experiments, the proton is a target which is probed by very short-wave length electrons. Electrons produced by a high-energy linear accelerator are scattered from protons to study the electric charge distribution in a proton.

Questions concerning the structure of the proton or the neutron are difficult due to the ambiguity of experimental results. One cause of uncertainty is that the probe is not defined in sufficient detail. It appears desirable to use a strong interaction probe, that is, another nucleon or meson, but the structure of the probe may be no better understood than the structure of the target.

A mantle of mesons has been found about the proton. A current question is whether or not there is an internal or intrinsic core of a proton.

PULSE GENERATION

Pulse waveforms are distinguished by abrupt, often almost discontinuous features. Such features may serve as time markers: pulses can carry information in the time domain (e.g., in computers). Also, such waveforms can have a very low duty cycle (= fractional time the pulse is present); pulses can supply momentary large bursts of power to equipment whose average rating is relatively low (e.g., high-power microwave pulse transmitters for radar).

The fundamental element in pulse generation is the switch. Opening or closing a switch generates a step-function pulse (e.g., in key telegraphy); one or more such steps, together with suitable wave-shaping operations, may yield the final desired waveform.

For low-level pulses, overdriven amplifiers (transistors or vacuum tubes) are commonly used as switching elements. The simplest example is that of a *clipping amplifier*; when driven by a large sinusoid, this produces an approximately square-wave output whose abrupt level changes may serve as sources of pulse waveforms. The transition *rissetime*, beyond its dependence on the driving signal, is limited by amplifier properties such as internal capacitances and charge storage (in transistors). Low-power transistors may have rissetimes of the order of nanoseconds; high-power units are typically an order of magnitude slower.

Two amplifiers can be cross-connected to drive each other alternately over the switching range. Depending on the coupling circuits, the pair can be bistable, monostable, or astable (Fig. 1). The *univibrator* rests in its quiescent state until driven into the other by the trigger pulse; it relapses into the rest state after a time determined by the R-C coupling, approximately given by $RC \ln(1 + V_{cc}/V_{bb})$. Thus the trigger produces an output of standardized amplitude and width. The *multivibrator*, with two R-C couplings, free-runs and thus serves as pulse source (clock). Timing (or frequency) stabilities of order 1 per cent are typical.

The *blocking oscillator* is a single amplifier which drives itself over the switching range by means of transformer feedback. A monostable arrangement is shown in Fig. 2. The transistor is

FIG. 2. Monostable blocking oscillator.

brought momentarily into conduction by the trigger pulse; thereafter it drives itself into saturation. The width of the output pulse is determined mostly by the transformer properties, above all by the magnetic saturation of the core. The regenerative self-drive permits the blocking oscillator to supply relatively large currents to the load.

Steps and rectangles can be shaped into other forms by many techniques.¹ Three classes (linear, nonlinear, and delay-line shaping) are typified by the examples in Fig. 3. The delay-line circuit produces a narrow rectangle from a step; the trailing edge is formed by the reflection of the leading edge in the unmatched delay line. The pulse falltime is thus as short as the rissetime, within the limitations of the delay line response.

Whenever possible, switching and shaping are carried out directly at the output power level. In that case, the energy in the delivered pulse may come from that stored in the pulse-forming network, the switch dissipation being negligible (current and voltage not present simultaneously);

FIG. 1. Univibrator (monostable) and multivibrator (astable). If both cross-couplings are resistive, a bistable binary results; this requires a trigger on either side to change state.

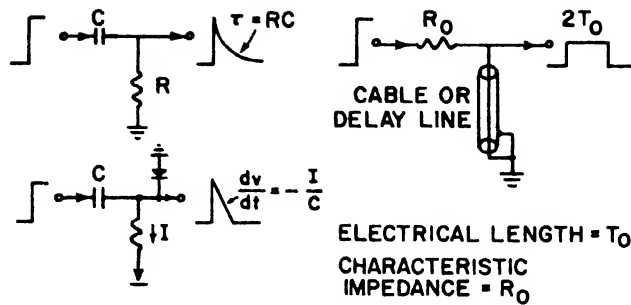

FIG. 3. Examples of shaping circuits to produce short pulses from a step.

the power supply recharges the network slowly between pulses. For some shapes, the forming process is inefficient and must be carried out at low level; a linear output amplifier is then required. This, as well as the supply, must momentarily handle large power. Vacuum-tube amplifiers are common in this type of service (voltages up to about 50 kV, currents to several tens of amperes).

Some other types of switching element are listed below:

(a) *Mechanical Switches* (usually reed relays with mercury-wetted contacts to eliminate bounce) may generate steps with sub-nanosecond risetime. The electromechanical drive limits the frequency to a few hundred cycles per second.

(b) *Unijunction Transistors*² (double-base diodes) switch regeneratively when the emitter becomes forward biased; the injected carriers increase the conductivity of the base material. Switching times of the order of 1 μ sec are typical.

(c) *Thyratrons* (hot-cathode gas- or vapor-filled tubes). A discharge is initiated by a trigger signal applied to the grid. To extinguish the discharge, the anode must be reverse-biased; the deionization time (of order 100 μ sec) limits the minimum pulse spacing. Extremely high power levels may be handled: up to about 50 kV, 5 kA. The risetime is as short as a few nanoseconds in hydrogen tubes. Figure 4 shows a pulse modulator for a microwave klystron. The

power stored in the pulse-forming network is delivered to the load via a pulse transformer. Recharge takes place through a "ringing choke," avoiding the power loss associated with a charging resistor.

(d) *Ignitrons, Triggered Spark Gaps*. These are high-power gaseous discharge switches. Spark gaps are simple and produce extremely short risetimes, but electrode erosion may be a problem.

(e) *Controlled Rectifiers*³ (pnpn devices) have operating characteristics in many ways similar to those of thyristors. In most types, the load current must be interrupted to restore the non-conducting state; some low power devices (controlled switches) can be turned off by their control electrode. Risetimes are typically of order 1 μ sec.

(f) *Avalanche Transistors*⁴. Collector-to-emitter breakdown may occur regeneratively with sub-nanosecond risetime in certain transistors. This may be initiated by overvoluting the collector or by suddenly changing the base potential. Avalanche transistors can generate fast, large pulses (e.g., 30 volts) at high repetition rates (e.g., 5 Mc/sec).

(g) *Tunnel Diodes*⁵. Heavily doped diodes have extremely thin depletion layers through which quantum-mechanical tunneling of majority charge carriers can occur over a narrow voltage range (about 0.1 volt). At higher voltage, after a sharp drop of this tunnel current, ordinary injection

FIG. 4. High-power pulser using hydrogen thyatron.

current sets in (about 0.5 volt). The diode may switch from tunneling to injection voltage at sub-ns speed. Choice of loadline results in bistable, monostable, or astable operation; transitions may be provoked by suitable current signals. The voltage level of operation is very low (about 0.5 volts).

(h) *Snap Diodes*⁸. Stored charge resulting from a period of forward conduction causes a diode to conduct freely when reverse bias is first applied. In special step-recovery diodes, this reverse current ceases abruptly (with sub-nanosecond falltime), and the resulting opening of the switch can generate fast pulses at high repetition rates (100 Mc/sec) and relatively high level (tens of volts).

PYROMETRY, OPTICAL

Optical pyrometry is that branch of thermometry in which the temperature of a solid or liquid is determined by measuring the radiation emitted in a relatively narrow spectral region. The International Practical Temperature Scale (IPTS) above the melting point of gold (1336.15°K) is defined in terms of such radiation, and an optical pyrometer is usually used to realize the IPTS above this temperature.

Figure 1 is a schematic diagram of a common type of optical pyrometer. The objective lens (B) images that part of the source (A) for which the temperature is to be determined in the plane of the filament of the pyrometer lamp (E). The microscope (G, H, I) magnifies the source image and the small pyrometer lamp filament by a factor of about fifteen. The red filter (F) and the spectral response of the eye limit the spectral band pass of the instrument to wavelengths from about 6200 to 7100Å with the effective value about 6500Å. The absorption filter (D) is inserted at source brightness temperatures above about 1300°C so that the pyrometer lamp

need not be operated at higher temperatures where its stability is poor.

The optical pyrometer shown in Fig. 1 is operated by adjusting the current in the pyrometer lamp filament until the brightness of the filament equals the brightness of the image of the source.

FIG. 1. Schematic diagram of a disappearing filament optical pyrometer. A. Source; B. Objective lens; C. Objective aperture; D. Absorption filter (used for temp. above 1300°C); E. Pyrometer lamp; F. Red filter; G. Microscope objective lens; H. Microscope aperture stop; I. Microscope ocular; J. Eye; K. Current measuring instrument.

From this current and a previous calibration of the pyrometer, the brightness temperature of that part of the source or object sighted upon can be determined. The brightness temperature of an object is defined as the temperature of a blackbody which emits the same spectral radiance as the object. Spectral radiance is defined as the quotient of the radiant power emitted at a particular wavelength and in a particular direction by the product of the wavelength interval, the solid angle and the emitting area projected perpendicular to the direction of sighting. If the object is a blackbody, the brightness temperature of the blackbody is its temperature. If the object is not a blackbody, the temperature of the object can be obtained from its brightness temperature and the equation

$$\epsilon_{\lambda} = \frac{e^{C_2/\lambda T} - 1}{e^{C_2/\lambda T_B} - 1} \quad (1)$$

where ϵ_{λ} is the spectral emissivity (also called spectral emittance), λ is the wavelength, in centimeters, at which the pyrometer is effectively operating (usually about 0.65×10^{-4} cm), C_2 is the second radiation constant (1.438 centimeter degrees on the IPTS), T_B is the brightness temperature and T is the temperature, both in degrees Kelvin. The spectral emissivity of a surface is the fraction of blackbody spectral radiance emitted by the surface when it has the same temperature as the blackbody. Spectral emissivities for a wavelength of 0.65×10^{-4} cm have been determined for a large number of materials. When $C_2/\lambda T$ is greater than about 5, Eq. (1) can be replaced, with negligible error, by the simpler equation

$$\frac{1}{T} = \frac{1}{T_B} + \frac{\lambda}{C_2} \ln \epsilon_{\lambda} \quad (2)$$

where \ln is the symbol for the natural logarithm.

The calibration of an optical pyrometer from basic principles is called a primary calibration and is usually performed in national standard laboratories such as the National Bureau of Standards. The first step of a primary calibration of an optical pyrometer is making a brightness match while sighting on a blackbody surrounded by freezing gold. The temperature of freezing gold is defined to be 1336.15°K on the International Practical Temperature Scale. Higher brightness temperature points are obtained by using the defining equation of the IPTS,

$$R = \frac{e^{c_2/\lambda T_n} - 1}{e^{c_2/\lambda T_{Au}} - 1} \quad (3)$$

Experimentally, the brightness temperature of a stable source is adjusted until the source, as seen through a rotating sector disk with transmittance R , has the same brightness as a gold blackbody. Independent measurement of R and λ then permit, from Eq. (3), a calculation of T_n . The pyrometer lamp current required for making a brightness match while sighting on the source without the sector disk completes the calibration at this higher temperature. This process is repeated with a sufficient number of sector disks and temperatures so that a smooth curve can be drawn relating current in the pyrometer lamp to the brightness temperature of the source.

With a well-designed optical pyrometer of the type in Fig. 1, it is possible to realize the IPTS in a primary calibration with an estimated uncertainty of ± 0.4 deg at 1336°K, ± 2.0 deg at 2300°K and ± 10.0 deg at 4300°K. The National Bureau of Standards also calibrates commercial pyrometers of the type in Fig. 1 by comparison to a primary calibrated pyrometer. The uncertainty of this comparison calibration is estimated to be ± 3 deg, ± 6 deg, and ± 40 deg respectively at the temperatures given above. These figures apply to brightness or blackbody temperatures. The accuracy with which an optical pyrometer can determine the temperature of a non-blackbody depends not only on the pyrometer calibration in terms of brightness temperature but also on the uncertainty of the spectral emissivity required. This often produces an error greater than the calibration uncertainties given above.

Recently (1960), photoelectric pyrometers have been developed which replace the eye with a photomultiplier tube and use an interference filter or monochromator to limit the spectral band pass. With the increased sensitivity and smaller band pass in these instruments, the International Practical Temperature Scale above 1336.15°K can be realized with about one-third the uncertainty possible with the visual instrument in Fig. 1. The present limitation in realizing the IPTS with a photoelectric pyrometer appears to be the instability of the pyrometer lamps. To improve the accuracy further, lamps with greater stability will have to be developed or a different type optical pyrometer designed, possibly one using only the gold-point blackbody as a reference source. The gold-point blackbody is at least a factor of ten more stable than pyrometer lamps.

In addition to optical pyrometers, total radiation pyrometers and two color pyrometers are sometimes used for measuring temperatures. Usually, however, these instruments are less accurate than optical pyrometers and are primarily intended for controlling temperature rather than for measuring it.

Q

QUANTUM ELECTRODYNAMICS

Broadly speaking, quantum electrodynamics is that branch of physics which studies the phenomena of interaction of radiation with matter subject to the laws of quantum mechanics. In recent years, it has been studied extensively not only to explain the results of experiments with photons and elementary particles and nuclei, but also to obtain a deeper understanding of the basic laws of physics. However, progress has been very slow, undoubtedly on account of the complexity of the problem and the lack of knowledge of the structure of elementary particles and the interacting forces at close ranges which account for their stability and the creation or annihilation of material particles and radiation. On the other hand, there is a greater understanding of the basic laws governing pure radiation and of its interaction with electrons and positrons. The theory of the electromagnetic fields and the electron-positron and their interaction subject to quantum laws are well understood, and in a proper sense, quantum electrodynamics dealing with Maxwellian and Dirac fields, free or in interaction with each other, is as complete as one could expect from our present knowledge of the electromagnetic field and the electron-positron pair, based on experimental evidence.

Quantization of Free Maxwellian Fields. In quantizing the electromagnetic field, one starts with the laws of classical electrodynamics based on Maxwell's equations. These may be written in the form

$$F_{\mu\nu,\rho} + F_{\nu\rho,\mu} + F_{\rho\mu,\nu} = 0 \quad (1a)$$

$$F_{\mu\nu,\nu} = 0 \quad (1b)$$

where $F_{\mu\nu}$ are the well-known components of the field, E and H . They can be derived also from a variational principle by taking a Lagrangian

$$L = -\frac{1}{2}F_{\mu\nu}F_{\mu\nu} \quad (2)$$

Usually, one works with the potentials A_μ^* , defined by

$$F_{\mu\nu} = A_{\nu,\mu} - A_{\mu,\nu} \quad (3)$$

* The Greek letters run from 1 to 4 for vectors or operators and the Latin indices from 1 to 3. In the coordinates, the Greek subscript takes the values 0, 1, 2, 3, and Latin letters, 1, 2, 3. Also $k = (\mathbf{k}, k_0) = (k_1, k_2, k_3, k_0)$, $x = (\mathbf{x}, x_0) = (x_1, x_2, x_3, x_0)$, the same notation holds for p, q ; $k_0 = \omega$ (omega), $x_0 = it$ and the units are $\hbar = c = 1$.

which satisfy the equation of propagation (motion)

$$\square A_\mu(x) - A_{\nu,\mu\nu}(x) = 0 \quad (4)$$

From Eq. (3) A_μ is determined up to a gradient of a scalar function $\Lambda(x)$, i.e.,

$$A_\mu^1 = A_\mu + \Lambda_{,\mu} \quad (5)$$

known as gauge transformation. The fields $F_{\mu\nu}$ and Eq. (4) remain invariant under such transformations.

The equation of motion [Eq. (4)] is simplified by introducing a subsidiary (Lorentz) condition on the potentials, namely

$$A_{\mu,\mu} = 0 \quad (6)$$

reducing Eq. (4) to

$$\square A_\mu = 0 \quad (7)$$

which together with Eq. (6) is equivalent to Maxwell's equations. However, condition (7) still does not determine uniquely A_μ , but now the gauge transformation restricts the class of functions Λ to solutions of the equation

$$\square \Lambda = 0 \quad (8)$$

On account of the photon mass $m = 0$, the fields $F_{\mu\nu}$ and not the potentials A_μ have a direct physical meaning. This, however, is not the case if $m \neq 0$.

The canonical (momenta) variables $\pi_\mu(x)$ corresponding to the Lagrangian Eq. (3) are

$$\pi_\mu = iF_{4\mu}(x) \quad (9)$$

and thus $\pi_4 = 0$. As a consequence, Eq. (9) cannot be solved by $A_{\mu,4}$. To avoid this difficulty, the Lagrangian Eq. (3) is replaced by the following

$$L = -\frac{1}{2}F_{\mu\nu}F_{\mu\nu} - \frac{1}{2}A_{\mu,\mu}A_{\nu,\nu} = -\frac{1}{2}A_{\mu,\nu}A_{\nu,\mu} \quad (10)$$

from which the canonical momenta are given by

$$\pi_l(x) = iF_{4l}(x) \quad (11a)$$

$$\pi_4(x) = iA_{\nu,\nu}(x) \quad (11b)$$

and hence instead of Eq. (8) we obtain the weaker condition

$$\square A_{\nu,\nu}(x) = 0 \quad (12)$$

which follows from Eq. (4). Furthermore, one does not take the general solution of the equation,

but only those which satisfy the initial conditions, say at $t = 0$,

$$A_{r,r}(x) = 0, A_{r,0r}(x) = 0, \text{ for all } x \quad (13)$$

then from Eq. (12) it follows that $A_{r,r}(x)$ vanishes for all t . This is in agreement with the usual formalization of the theory of electromagnetism.

To quantize the field, we take the Lagrangian Eq. (10) and apply the commutation rules to the canonical variables $A_\mu(x)$, $\pi_\mu(x)$ for $x_0 \rightarrow x'_0$, namely

$$\begin{aligned} [A_\mu(x), A_\nu(x')] &= 0, [\pi_i(x), \pi_k(x')] \\ &= A_{i,0}(x) - A_{k,0}(x') = 0 \\ [A_\mu(x), \pi_k(x')] &= [A_\mu(x), A_{k,0}(x')] \\ &= i\delta_{\mu k}\delta(\mathbf{x} - \mathbf{x}') \quad (14) \\ [A_4(x), \pi_4(x')] &= [A_4(x), iA_{r,0}(x')] \\ &= i\delta_{44}\delta(\mathbf{x} - \mathbf{x}') \end{aligned}$$

Now we expand $A_\mu(x)$ in a Fourier series in momentum space k

$$A_\mu(x) = \sum_k [e^{ikx} A(\mathbf{k}) + e^{-ikx} A(\mathbf{k})] \quad (15)$$

From Eq. (7) it is necessary that $k^2 = \mathbf{k}^2 = k_0^2$, so $k_0 = \pm \omega$, $\omega = \sqrt{\mathbf{k}^2}$. On the other hand, since $A_i(x)$ is hermitian and $A_4(x)$ antihermitian, it follows that $A_i(k)$, $iA_4(k)$ and $A_i(\mathbf{k})$, $iA_4(\mathbf{k})$ are hermitian conjugates of each other. Furthermore, for every \mathbf{k} , four possible (independent) polarizations e_μ^λ , $\lambda = 1, 2, 3, 4$ (orthogonal) can be assigned to $A_\mu(x)$, so Eq. (15) may be written in the form

$$A_\mu(x) = \frac{1}{\sqrt{2V}} \sum_k \sum_\lambda \frac{e_\mu^\lambda}{\omega} [e^{ikx} a^\lambda(\mathbf{k}) + e^{-ikx} a^{*\lambda}(\mathbf{k})],$$

$$(e_\mu^\lambda e_\mu^{\lambda'} - \delta_{\lambda\lambda'}) (k_0 = \omega) \quad (16)$$

In general e_μ^λ may be functions of k . We then choose e_μ^λ in such a way that

$$e_4^m = 0, e_m^1 k_m = e_m^2 k_m = 0, e_m^3 = k_m \omega^{-1},$$

$$e_m^4 = 0, e_i^4 = 1, (m = 1, 2, 3) \quad (17)$$

With this choice of the polarization vector e_μ^λ , its components for $\lambda = 1, 2$ represent transverse polarization, $\lambda = 3$, longitudinal (along \mathbf{k}) polarization and $\lambda = 4$ scalar polarization. Since condition (6) has not been imposed on $A_\mu(x)$, we also have $\sum_\lambda e_\mu^\lambda e_\nu^{\lambda'} = \delta_{\mu\nu}$ and from the choice $e_i^4 = 1$, $a^\lambda(\mathbf{k})$, $a^{*\lambda}(\mathbf{k})$ satisfy the same conditions as $A_\mu(\mathbf{k})$ and $A_\mu^*(\mathbf{k})$.

With $A_\mu(x)$ given by Eq. (17), the commutation relations of Eq. (14) now become

$$[a^\lambda(\mathbf{k}), a^{\lambda'}(\mathbf{k}')] = [a^{*\lambda}(\mathbf{k}), a^{*\lambda'}(\mathbf{k}')] = 0$$

$$[a^\lambda(\mathbf{k}), a^{*\lambda'}(\mathbf{k}')] = \delta_{\lambda\lambda'} \delta_{\mathbf{k}\mathbf{k}'} \quad (18)$$

by using the properties of e_μ^λ and the definition of the delta function.

From the Lagrangian function Eq. (10) one finds, after partial integration in \mathbf{x} , the Hamiltonian operator H to be

$$H = \frac{1}{2} \sum_{\mathbf{k}, \lambda} \{a^\lambda(\mathbf{k}), a^{*\lambda}(\mathbf{k})\} \omega \quad (19)$$

where $\{a, a^*\} = aa^* + a^*a$, symbolizes anticommutation. Introducing hermitian operators $q_\mathbf{k}^\lambda$, $p_\mathbf{k}^\lambda$ defined by

$$q^m = \frac{1}{\sqrt{2\omega}} (a^m + a^{*m}), p^m = i\sqrt{\frac{\omega}{2}} (a^m - a^{*m})$$

$$(m = 1, 2, 3)$$

$$q^4 = \frac{1}{\sqrt{2\omega}} (a^4 - a^{*4}), p^4 = i\sqrt{\frac{\omega}{2}} (a^4 + a^{*4}),$$

$$[p^\lambda, q^{\lambda'}] = i\delta_{\lambda\lambda'} \quad (20)$$

H takes the form

$$H = \frac{1}{2} \sum_{\mathbf{k}} \left\{ \sum_{\lambda=1}^3 [(p^\lambda)^2 + (q^\lambda)^2] + [(p^4)^2 + (q^4)^2] \right\} \quad (21)$$

which resembles the Hamiltonian operator for a sum (infinite in our case) of independent harmonic oscillators. Therefore, the energy operator H and its eigenvalues are

$$H = \sum_{\mathbf{k}} \left\{ \sum_{m=1}^3 N^m(\mathbf{k}) + N^4(\mathbf{k}) \right\} \omega,$$

$$E = \sum_{\mathbf{k}} \omega \left\{ \sum_{m=1}^3 n^m(\mathbf{k}) + n^4(\mathbf{k}) \right\},$$

$$(N^m = a^{*m} a^m, N^4 = a^4 a^{*4}) \quad (22)$$

In Eq. (22) the zero-point energy of the oscillators (infinite) has been neglected. It represents the polarization of the vacuum, which for free fields does not play an important role. However, this is not true if sources or interaction with particles are considered.

A similar calculation leads to the following expression for the moment of momentum

$$P_m = \frac{1}{2} \sum_{\mathbf{k}} \{a^\lambda(\mathbf{k}), a^{*\lambda}(\mathbf{k})\} k_m$$

$$= \sum_{\mathbf{k}} k_m \left\{ \sum_{\lambda=1}^3 N^\lambda(\mathbf{k}) + N^4(\mathbf{k}) \right\} \quad (23)$$

where the zero-point contribution has been neglected. Equations (12) and (23) show the corpuscular aspect of the electromagnetic field. However, they include negative terms, i.e., both E and P_m may take negative values, in contradiction to the classical theory. Furthermore, H includes, besides transverse photons ($\lambda = 1, 2$), longitudinal ($\lambda = 3$) and scalar photons ($\lambda = 4$), in contradiction to our concept of light. In a correct theory, the last two kinds of photons should not appear in Equations (22) to (23).

Before describing the method of eliminating longitudinal and scalar photons, we shall briefly discuss the case when the commutation rules are

valid at different times. In this case, the time part in the expressions do not cancel, so instead of Eq. (14), we have the following result:

$$[A_\mu(x), A_\nu(x')] = \frac{1}{V} \sum_{\mathbf{k}, \lambda} \frac{e_{\mu\lambda} e_{\nu\lambda}}{2\omega} [e^{ik(x-x')} - e^{-ik(x-x')}] \\ = -i\delta_{\mu\nu} D(x' - x) \quad (24)$$

where the singular function $D(x)$ is defined by

$$D(x) = i(2\pi)^{-3} \int e^{ikx} \delta(k^2) \epsilon(k) dk \\ \delta(k^2) = \delta(k^2 - k_0^2) = \frac{1}{2|k|} [\delta(|\mathbf{k}| - k_0) + \\ + \delta(|\mathbf{k}| + k_0)], \quad \epsilon(k) = \frac{k_0}{|k_0|} \quad (25)$$

The function $D(x)$ satisfies the following properties:

$$D(x) = 0 \text{ for } x^0 > 0, \quad D(x)_{x_0} = -\delta(\mathbf{x}) \text{ for } x_0 = 0, \\ \square D(x) = 0 \quad (26)$$

This form of commutation rule is relativistic invariant, making the commutator of two fields a c -number. If interactions with particles or external fields are included, the result is a q -number.

Let $|0\rangle$ be the state vector of null particles. Then the expectation value of the anticommutator $\{A_\mu(x), A_\nu(x')\}$ is a matrix given by

$$\langle 0 | \{A_\mu(x), A_\nu(x')\} | 0 \rangle = (\delta_{\mu\nu} - \delta_{\mu 4} \delta_{\nu 4}) D^1(x' - x) \\ D^1(x) = (2\pi)^{-3} \int e^{ikx} \delta(k^2) dk \quad (27)$$

With the aid of $D(x)$ and $D^1(x)$ one can construct the corresponding functions for the retarded, advanced and mixed potentials which play important roles in quantum electrodynamics. All these functions satisfy the non-homogeneous equation $\square D_\mu = -\delta_\mu(x)$. In fact, when the mass $m \neq 0$, $D(x)$ is modified by replacing $\delta(k^2)$ by $\delta(k^2 + m^2)$ in Eq. (25).

In our derivation of Eq. (21) and (22), we have not used Lorentz condition (6), since it is incompatible with the commutation relations of Eq. (14). The potentials $A_\mu(x)$ or the $a^\lambda(\mathbf{k})$, $a^{*\lambda}(\mathbf{k})$ are operators acting on state functions $|\psi\rangle$; the Lorentz condition must be modified so that it is compatible with the commutation rules. This is done by requiring that

$$\langle A_\nu, a(x) | \psi(x) \rangle = 0 \quad (6')$$

$$\langle \psi | A_{\nu,r}(x) | \psi \rangle = 0 \text{ (expectation value of } A_{\nu,r}) \quad (6'')$$

However, since the state functions $|\psi\rangle$ cannot be normalized, one introduces a "metric operator" η and define the norm of a state vector to be: Norm $|\psi\rangle = \langle \psi | \eta | \psi \rangle$. As the norm should be a real quantity, η must be hermitian, $\eta^* = \eta$ and one assumes $\eta^2 = \eta \eta^* = 1$. Similarly the expectation value of any operator H is expressed in the form

$$H^{**} = \langle \psi | \eta H | \psi \rangle \quad (28)$$

From the new definition of normalizing the state functions and from Eq. (28) one deduces

$$\langle \psi | \eta A_k(x) | \psi \rangle = \langle \psi | A_k^*(x) \eta^* | \psi \rangle = \\ = \langle \psi | A_k(x) \eta | \psi \rangle \\ \langle \psi | \eta A_4(x) | \psi \rangle = \dots = \langle \psi | A_4 \eta | \psi \rangle \quad (28a)$$

We find for the commutators and anticommutators in ordinary and momentum space

$$[A_m(x), \eta] = 0, \quad [a^\lambda(\mathbf{k}), \eta] = 0, \quad \lambda \neq 4 \\ \{A_4(x), \eta\} = 0, \quad \{a^4(\mathbf{k}), \eta\} = 0 \quad (28b)$$

It follows from these relations that $\langle n^\lambda(\mathbf{k}) | \eta | n'^\lambda(\mathbf{k}) \rangle = \delta_{nn'}$, $\lambda \neq 4$ and

$$\langle n^4 | \eta | n'^4 \rangle = \delta_{nn'} (-1)^{n^4}$$

Applying the subsidiary condition Eq. (6') by using the operators $a^\lambda(\mathbf{k})$, we have

$$[a^3(k) + ia^4(k)] | \psi \rangle = 0 \quad (28c)$$

or in k -space (28) is written as

$$A^+_{\nu,r}(x) | \psi \rangle = 0 \quad (29)$$

where $A^+(x)$ represents the positive frequency part of $A(x)$, i.e., the term with e^{ikx} . Denoting $A^-(x)$, the negative frequency part of $A(x)$, we must also have $\langle \psi | A_{\nu,r}^-(x) | \psi \rangle = 0$. Equation (6'') for the expectation value of $A_\mu(x)$ now becomes

$$\langle \psi | \eta A_{\nu,r}(x) | \psi \rangle = 0 \quad (30)$$

The new subsidiary condition, now allows many independent solutions of Eq. (28). Any state vector $|\psi\rangle$ can be represented in the form

$$|\psi\rangle = |\psi_T\rangle \Pi \phi_k \quad (31)$$

Inserting this expression in Eq. (28), we obtain a fundamental solution by choosing

$$|\phi^0\rangle = |0, 0\rangle, \quad |\phi^1\rangle = |1, 0\rangle + i|0, 1\rangle, \dots, \\ |\phi^n\rangle = \sum_{r=0}^n i^r \sqrt{\binom{n}{r}} |n-r, r\rangle, \dots \quad (32)$$

All the vectors $|\phi^n\rangle$ are orthogonal to each other and their norms are not negative. In fact all, the norms of $|\phi^n\rangle$ vanish, except for that with $n=0$. Thus we have

$$\langle \phi^n | \eta | \phi^{n'} \rangle = 0, \quad n \neq n', \quad \langle \phi^n | \eta | \phi^n \rangle = \delta_{n0} \quad (33)$$

To satisfy Eq. (28) we normalize $|\phi^0\rangle$ to one and so we can express the vectors

$$|\phi_k\rangle = |\phi_k^0\rangle + \sum_{n \neq 0} c^n(\mathbf{k}) |\phi^n(\mathbf{k})\rangle \quad (34)$$

where the $c^n(\mathbf{k})$ are arbitrary. In terms of a^λ , Eq. (28) yields the following relation

$$a^3 |\phi^n\rangle = \sqrt{n} |\phi^{n-1}\rangle, \quad a^4 |\phi^n\rangle = i \sqrt{n} |\phi^{n-1}\rangle,$$

and the expectation values of $a^3(\mathbf{k})$, $a^4(\mathbf{k})$ reduce to the simple expressions

$$\langle \phi_k \eta a^3(\mathbf{k}) | \phi_k \rangle = C^1(\mathbf{k}), \quad \langle \phi_k \eta a^4(\mathbf{k}) | \phi_k \rangle = i C^1(\mathbf{k}) \quad (35)$$

On the other hand, the expectation value of A_μ is, from Eq. (5), given by

$$\langle \psi | \eta A_\mu(x) | \psi \rangle = \Lambda_{,\mu}(x) \quad (36)$$

Then on account of Eq. (36), Λ may be expanded in the form

$$\Lambda(x) = \frac{i}{\sqrt{V}} \sum_k \frac{1}{\sqrt{2}\omega^3} [c^{*1}(\mathbf{k})e^{-ikx} - c^1(\mathbf{k})e^{ikx}] \quad (37)$$

where the coefficients c^1 and c^{*1} are chosen so that Eq. (37) satisfies Eq. (8). Therefore, the expansion of a state vector according to Eq. (33) eliminates all the difficulties resulting from the Lorentz condition (6) and also the presence of scalar and longitudinal photons in the energy of the field, since the terms with coefficients $c^a(\mathbf{k})$ do not contribute any eigenstate to the Hamiltonian operator. The expectation value of the energy is now given only in terms of transverse photons, since only the state vectors $|\phi^0\rangle$ contribute to the Hamiltonian operator. The expectation value of H has now the form

$$\langle \psi | \eta H | \psi \rangle = \sum (n_k^1 + n_k^2) \omega \quad (38)$$

The vacuum state is made up of a mixture of longitudinal and scalar photons only, i.e., the vacuum is a state devoid of particles, (photons) which we have denoted by the state vector $|0\rangle$.

Quantization of the Free Dirac Field. The quantizations of the free Dirac field can be carried out in a similar manner as for the Maxwell free field, by making appropriate modifications for the inclusion of a finite mass and charge. The equation of motion of free electrons is the Dirac equation

$$(\gamma_\mu \partial_\mu + m)\psi_\mu(x) = 0 \quad (39)$$

where γ_μ are Dirac matrices, γ_4 being expressed by Pauli matrices and $\gamma_4 = \begin{pmatrix} I & 0 \\ 0 & -I \end{pmatrix}$. With this choice of γ_μ , and the adjoint $\bar{\psi}(x) = \psi^*(x)\gamma_4$, where $\psi^*(x)$ is the hermitian adjoint of ψ , $i\bar{\psi}(x)\gamma_\mu\psi(x)$ is invariant.

We now express a solution of Eq. (39) in a plane wave form

$$\psi_\mu(x) = u_\mu(\mathbf{q})e^{i(\mathbf{q}\mathbf{x} - q_0x_0)} \quad (40)$$

Substituting this in Eq. (39) one obtains four independent solutions $u_{\mu r}(\mathbf{q})$, two solutions, $r = 1, r = 2$, for positive q_0 and two for $r = 3, r = 4$ for $-q_0$, where $q_0 = \pm E = \pm \sqrt{\mathbf{q}^2 + m^2}$. These solutions are normalized in such a way that

$$\sum_{\mu=1}^4 u_{\mu r}(\mathbf{q})u_{\mu s}(\mathbf{q}) = \delta_{rs} \quad (41)$$

$$\sum_{r=1}^4 u_{\mu}^{*r}u_{rr} = \delta_{\mu\nu}, \sum_{r=1}^2 \bar{u}_{\mu}^r u_{rr} = -(2E)^{-1}(i\gamma q^+ - m)\nu_\mu, \quad (42)$$

$$\sum_{r=3}^4 \bar{u}_{\mu}^{-r} u_{rr} = (2E)^{-1}(i\gamma q^- - m)\nu_\mu$$

where $\bar{u}(\mathbf{q}) = u^*(\mathbf{q})\gamma_4$, and $q^+ = (\mathbf{q}, E)$, $q^- = (\mathbf{q}, -E)$. Equations (41) and (42) are the orthogonality and completeness relations.

The Lagrangian, the Hamiltonian and the current density of the fields are of the form

$$L = -\bar{\psi}(x)\left(\gamma \frac{\partial}{\partial x} + m\right)\psi(x) \quad (43)$$

$$H = -i\pi_\psi(x)\gamma_4(\gamma_\lambda \partial_\lambda + m)\gamma(x) \quad (44)$$

$$j = ie\bar{\psi}(x)\gamma_\mu\psi(x) \quad (45)$$

In the theory of quantization of the Dirac field, the functions $\psi(x)$, $\bar{\psi}(x)$ are considered as operators acting on state functions unlike that of the ordinary theory, where ψ is a state function. This procedure is known as second quantization of the electrons and $\bar{\psi}(x)\psi(x)$ does not have a probability interpretation as in the ordinary Dirac theory.

Developing the field functions $\psi(x)$ in plane waves, as was carried out for Maxwellian fields, in q -space we write

$$\psi_\mu(x) = \frac{1}{\sqrt{V}} \sum_q \left\{ e^{i(\mathbf{q}\mathbf{x} - Et_0)} \sum_{r=1}^2 u_{\mu r}(\mathbf{q})a^r(\mathbf{q}) + e^{i(\mathbf{q}\mathbf{x} + Et_0)} \sum_{r=3}^4 u_{\mu r}(\mathbf{q})a^r(\mathbf{q}) \right\} \quad (46)$$

and substituting it in Eq. (44) and (45), we obtain for the Hamiltonian operator and charge Q

$$H = \sum_q E \left\{ \sum_{r=1}^2 a^{*r}(\mathbf{q})a^r(\mathbf{q}) - \sum_{r=3}^4 a^{*r}(\mathbf{q})a^r(\mathbf{q}) \right\} \quad (47)$$

$$Q = e \sum_q \sum_{r=1}^4 a^{*r}(\mathbf{q})a^r(\mathbf{q}) \quad (48)$$

To find the commutation relations for the $a^r(\mathbf{q})$, $a^{*r}(\mathbf{q})$, one makes use of the property that the commutator of H with a field operator F is equal to $-iF$. From Eqs. (46) and (47), we find the following anticommutation rules

$$\{a^{*r}(\mathbf{q}), a^s(\mathbf{q})\} = \delta_{rs}\delta_{\mathbf{q}\mathbf{q}'}, \{a^{*r}(\mathbf{q}), a^{*s}(\mathbf{q}')\} = 0 \\ \{a^r(\mathbf{q}), a^s(\mathbf{q}')\} = 0 \quad (49)$$

Now the total energy can be written in terms of the particle numbers, N^+ , N^- ,

$$H = \sum_q E \left\{ \sum_{r=1}^2 (N^{+r}(\mathbf{q}) - N^{-r}(\mathbf{q}) - 2) \right\} \\ N^{+r} = a^{*r}(\mathbf{q})a^r(\mathbf{q}), N^{-r} = b^{*r}(\mathbf{q})b^r(\mathbf{q}), \\ b^1(\mathbf{q}) = a^{*4}(-\mathbf{q}), b^2(\mathbf{q}) = a^{*3}(-\mathbf{q}) \quad (50)$$

It is not difficult to see that $N^+(1 - N^+) = N^-(1 - N^-) = 0$. The last term of Eq. (50) represent an infinite energy, the so-called zero-point energy of the field. Therefore, the eigenvalues of N^+ and N^- are 0 and 1, and from the anticommutation relations of Eq. (49), for any given state there is only one electron in agreement with Pauli's principle.

In a similar manner, one finds the following expression for the total charge

$$Q = e \sum_{\mathbf{q}, r} \{N^+{}^r(\mathbf{q}) - N^-{}^r(\mathbf{q})\} \quad (51)$$

where the zero-point part has been neglected. This expression for the charge is not positive definite. The interpretation given to N^+ and N^- is that for the positive part of the energy, and negative e , N^+ denotes the number of electrons, and for the negative part of the energy, and $+e$, N^- represents the number of positrons.

The zero-point term in Eq. (51) when formulated in x -space must yield a value for the expectation of the current density $j_\mu(x)$ for the vacuum.

This can be done by taking $j_\mu(x) = \frac{ie}{2} [\bar{\psi}(x) \gamma_\mu \psi(x)]$ instead of Eq. (45). Using Eq. (46), one arrives directly at Eq. (51) and also obtains $\langle 0 | j_\mu(x) | 0 \rangle = 0$, where $|0\rangle$ is the state vector of the vacuum.

The ordinary components of the momentum are obtained from the expansion of Eq. (46), as follows:

$$P_k = i \int d^3x \bar{\psi}(x) \gamma_k \psi(x)_{,k} = \sum_{\mathbf{q}, r} \hbar \mathbf{q} \cdot (N^+{}^r(\mathbf{q}) - N^-{}^r(\mathbf{q})) \quad (52)$$

From the definition of b^{\pm} Eq. (50), the last term in Eq. (46) is the creation operator for the positrons. The angular momenta can also be calculated from the expression of the energy-momentum tensor $T_{\mu\nu}(x)$. Its space components are made up of terms which are independent of the polarization state of the particles (ordinary angular momenta), and terms along the direction of motion for any electron state. If z is the direction of motion, then for an electron state $|q\rangle$, and position state $|q'\rangle$, the latter terms are

$$J_{12}{}^1 |q\rangle = \frac{1}{2} (-1)^{r-1} |q\rangle, \quad J_{12}{}^1 |q'\rangle = \frac{1}{2} (-1)^{r-1} |q'\rangle \quad (53)$$

In the expression for the charge [Eq. (51)], N^+ and N^- correspond to the electron and positron particle if e is taken negative and have a reverse role if e is assigned a positive value.

Therefore the theory is invariant with respect to the transformation $N^+ \leftrightarrow N^-$, and at the same time $+e \leftrightarrow -e$. This invariant property can be formulated also for the field operators $\psi(x)$ in x -space. Remembering that $\bar{\psi}(x)$ is the annihilation operator for the electrons, but the creation operator for the positron, and the reverse for $\bar{\psi}(x)$ or $\psi(x)$, the transformation $N^+ \leftrightarrow N^-$ corresponds to an interchange of $\bar{\psi}(x)$ and $\psi(x)$. This symmetry is not preserved for charge transformations, so the transformation with respect to charge reversal (conjugation) is expressed in a more complicated form.

$$\psi_A(x) \rightarrow \psi_B^+(x) = C_{AB} \bar{\psi}_B(x), \quad C_{AB} = -C_{BA},$$

$$(C^{-1})_{AB} = (C_{BA})^*, \quad (C^{-1} \gamma_\mu C)_{AB} = -(\gamma_\mu)_{AB} \quad (54)$$

These properties of C make it possible for $\bar{\psi}'(x)$ to satisfy the same equation as $\psi(x)$, leave $j_\mu(x)$ invariant, and $\psi'(x)$ can be developed in a series similar to Eq. (46). However, the Lagrangian [Eq. (43)] is no longer invariant and symmetric with respect to charge conjugation. To preserve these properties one introduces a new Lagrangian

$$L = \frac{1}{4} \left[\bar{\psi}(x) \left(\gamma \frac{\partial}{\partial x} + m \right) \psi(x) \right] - \frac{1}{4} \left[\frac{\partial \bar{\psi}(x)}{\partial x} \gamma + m(x) \right] \psi(x) \quad (55)$$

from which one obtains the correct equations of motion and the energy momentum tensor $T_{\mu\nu}$. By choosing the matrix $C = \gamma_2 \gamma_4$, then C is a unitary matrix, with the property, $C^{-1} \gamma_\mu C = \gamma_\mu$, $\mu = 2, 4$ and $+\gamma_\mu$ for $\mu = 1, 3$, and the vacuum expectation value of the current density, $\langle 0 | j_\mu(x) | 0 \rangle = 0$, is preserved. Furthermore, one can calculate in a similar way as for the electromagnetic case the commutators and anticommutators of $\bar{\psi}(x)$ and $\psi(x')$, in x -space using the development of Eq. (46). The result of summing over the index r leads, with the aid of Eq. (42), to the following expression for the anticommutator

$$\{\bar{\psi}_A(x), \psi_B(x')\} = -S_{BA}(x' - x) \quad (56)$$

$$S_{AB} = -i(2\pi)^{-3} \int dq e^{iqx} (i\gamma q - m)_{AB} \delta(q^2 + m^2) \epsilon(q) \quad (57)$$

where the singular function S plays the same role as $D(x)$ for Maxwellian fields, and moreover, it is a solution of Dirac's equation with initial conditions $\psi(x) = u(x)$ for $x_0 = T$. From S , we can construct the corresponding retarded and advanced functions S_R , S_A , and the mixed function S_F , satisfying Dirac's Eq. (1) with a non-homogeneous term $2i\delta(x)$. On the other hand, the vacuum expectation value of the commutator, $\bar{\psi}(x)$, $\psi(x)$ is expressed in terms of the singular function

$$S^1(x) = (2\pi)^{-3} \int dp e^{ipx} (i\gamma p - m) \delta(m^2 - p^2),$$

which does not vanish for space-like points, but vanishes for $x_0 = x'_0$ as required by the theory. The function $S^1(x)$ plays the same role as $D^1(x)$ in Maxwell theory.

Free Maxwellian and Dirac Fields in Interaction. One of the most important problems in quantum electrodynamics is that of interaction of electrons with radiation fields. One of the great successes of quantum electrodynamics is to be found in predicting and explaining a large number of phenomena related to behavior of electrons and photons in interaction, such as the Lamb shift, magnetic moment of the electron, and collision processes. These achievements are possible on account of the weak interaction between electrons and photons. However, the theory is beset by a number of serious difficulties, mainly due to the effect of the vacuum on the mass and charge of the electrons.

The equations of motion of an electron interacting with a Maxwellian field can be derived from a Lagrangian L

$$L = L_e + L_M + L_i \quad (58)$$

where L_e and L_M are the Lagrangians of the free Dirac and Maxwell field, and L_i is the interaction Lagrangian given by the expression

$$L_i = \frac{ie}{2} A_\mu(x) [\bar{\psi}(x), \gamma_\mu \psi(x)] - A_\mu(x) j_\mu(x) \quad (59)$$

From the Lagrangian function, one derives the equation of motion in the usual way

$$\left(\gamma \frac{\partial}{\partial x} + m \right) \psi(x) = ie \gamma A(x) \psi(x) \quad (60)$$

$$\square A_\mu(x) = \frac{ie}{2} [\bar{\psi}(x), \gamma_\mu \psi(x)] - j_\mu(x) \quad (61)$$

Since L_i does not contain time derivatives of the field operators, the quantization is carried out as previously. The commutation relations, the operators $A(x)$, $\psi(x)$, are unchanged as for free fields, but we have in addition

$$[A_\mu(x), \psi(x)] = [A_{\mu, x_0}(x), \psi(x')] = 0 \text{ for } x_0 = x'_0$$

$$[A_\mu(x), \bar{\psi}(x')] = [A_{\mu, x_0}(x), \bar{\psi}(x')] = 0 \quad (62)$$

However, one cannot extend the commutation relations to different times in a simple way as for the free fields, since Eqs. (60) and (61) do not have simple solutions and, as we have remarked, they no longer lead to c -numbers as for free fields.

The integration of the equations of motion (coupled equations) can be done by the method of Picard (successive approximation), providing the coupling parameter is small. In general, with the aid of the functions S_R and S_A , one can transform them to coupled integral equations, where S_R and S_A are the Green functions of the problem. The usual method is to apply perturbation theory by expanding $\psi(x)$, $A_\mu(x)$ in series of the coupling constant (fine structure constant), with the leading terms taken as solutions of the free field equations. This procedure is satisfactory as long as we do not take account of the effect of the vacuum, which introduces changes in the mass and the charge of the electron which are expressed by divergent integrals. By a process known as *renormalization*, the infinities entering in the expressions of variations in mass and charge, δm and δe , can be made to disappear, so that the total mass and charge are the physical measured quantities. In this way, meaningful results can be assigned to the elements of the matrix representing physical quantities.

The source of these infinities arises from the fluctuations of the vacuum states of the electromagnetic field and the electron-positron pairs, even though their expectation values vanish. Thus, the interaction of an electron with the vacuum states produces a change in its energy through the variation of mass (renormalization

effect) and also affects the electron-positron state, which in turn changes the state of polarization of the vacuum, manifested in an apparent change of charge of the electron (charge renormalization). Even though one is able to extract meaningful results from the renormalization procedure, it is found to be not unitary, and unless convergence is established in a unique way, negative norms may creep into the energy operator which would lead to meaningless negative probabilities. Another difficulty enters into the picture when strong interactions come into play (high energies) with the creation of mesons, since perturbation procedures fail. Even other mathematical methods (asymptotic procedures) have not yielded many useful results, on account of the mathematical complexity of the problem. Likewise for very small intervals, the geometry may no longer be Minkowskian or even Riemannian, and the present concept of space and time would have to be modified in order to make the theory free of the divergencies appearing in the integrals representing the operators and also in the renormalization process. In spite of these grave difficulties in the theory, that part of quantum electrodynamics dealing with photon and electrons, free and in interaction with each other, will not be affected very much by new developments.

QUANTUM THEORY

Experiments on thermal radiation, with their gross disagreement with classical theories, gave birth to quantum theory. The equilibrium distribution of electromagnetic radiation (that is, emission and absorption of radiation at constant temperature) in a hollow cavity could not be explained on the basis of classical electrodynamics (Maxwell's equations plus the laws of motion of particles). Thermal radiation is a certain function of the temperature (T) of the emitting body. When dispersed by a prism, thermal radiation forms a continuous spectrum. It was found that

the energy distribution of the radiation had a regular dependence on its wavelength. Furthermore the energy E_ν as a function of the temperature of the material did not depend upon the structure of the cavity or its shape. On these bases it was shown that the energy E_ν ought to have a dependence upon frequency ν , at temperature T , in the form

$$E_\nu = \nu^3 F\left(\frac{cT}{\nu}\right)$$

All attempts to find the correct form of F on the basis of classical theory failed. The classical theory led to the now well-known "ultraviolet difficulty," since the contribution of high frequencies caused the energy to assume infinite value. The difficulty was removed by a hypothesis of Planck, according to which the energy of a monochromatic wave with frequency ν can only assume those values which are integral multiples of energy $h\nu$; that is, $E_n = nh\nu$, where n is an integer referring to the number of "photons." Thus the energy of a single PHOTON of frequency ν is

$$E = h\nu \quad (1)$$

The finiteness of Planck's constant h and its resulting implications laid the foundations of quantum theory. Quantum theory, like the special theory of relativity, was discovered through the experiments on electromagnetic phenomena and their theoretical interpretations.

The fundamental equation of quantum mechanics [Eq. (1)] implies, on the one hand, that energy of radiation stays concentrated in limited regions of space in amounts of $h\nu$ and, therefore, behaves like the energy of particles; on the other hand, it establishes a definite relationship between the frequency ν and the energy E of an electromagnetic wave. This dual behavior of light corresponds, in one way, to experimental situations of the interference properties of radiation, for the description of which one uses the wave theory of light; in another way, it corresponds to the properties of exchange of energy and momentum between radiation and matter, which require for their explanation the particle picture of light. Thus the dual behavior of light has necessitated the quantum description (quantization) of the electromagnetic field. A unified point of view was formulated quantitatively by de Broglie, according to which all forms of energy and momentum related to matter will manifest a dual behavior of belonging to a wave or particle description of the physical system, depending on the type of experiment performed.

The most interesting example of a quantum mechanical object is the photon itself. By using the relativistic and quantum mechanical definition of the photon energy, we can obtain a quantitative formulation of the above ideas. The relativistic form of the total energy of a particle with rest mass m and momentum p is

$$E = c\sqrt{(p^2 + m^2c^2)} \quad (2)$$

We set $m = 0$ and obtain the relativistic definition of the energy of a photon:

$$E = cp \quad (3)$$

Hence the first unification of relativity and quantum theory originated from the combination of Eqs. (1) and (3) in the form

$$cp = h\nu \quad (4)$$

By using $\nu\lambda = c$ for the plane electromagnetic wave, we obtain the fundamental statement of quantum mechanics,

$$\lambda p = h \quad (5)$$

valid for all particles with or without mass, where

$$\lambda = \frac{h}{p}, \quad h = \frac{h}{2\pi}$$

These assumptions of quantum theory have laid the foundations of new physical and philosophical concepts for the process of measurement in physics and the definition of physical reality.

We need to develop a dynamical theory to describe the wave character of material particles. We shall base our approach on the idea that the concept of the photon must play a fundamental role in building a quantum theory of matter. To this end, a preliminary understanding of free photons in quantum theory will provide a first orientation, and it will set a clear path for further generalizations of the subject matter.

In the case of particles with mass, one has the possibility of comparing their kinetic energies with their rest masses. If the kinetic energy is small compared to rest energy then we can formulate a nonrelativistic theory. However, with the photon there exists no possibility for the formulation of a nonrelativistic theory. The theory of a free photon will have to be a relativistic one; it is a relativistic particle. There are important advantages in entering quantum mechanics via the photon:

(a) The energy of a photon is a quantum mechanical quantity, $E = h\nu$.

(b) It has provided a natural basis to postulate the wave-particle relation, $\lambda = h/p$.

(c) The wave aspects of the photon are completely described by charge-free Maxwell equations. Therefore, it is natural to try to reconcile Planck's hypothesis with the wave theory of light.

A reinterpretation of Maxwell's equations in conjunction with the quantum relations $E = h\nu$ and $\lambda = h/p$ will, in a natural way, lead us to a wave equation for the photon.

We begin with the free-field Maxwell equations

$$\frac{1}{c} \frac{\partial \mathcal{E}}{\partial t} - \nabla \times \mathcal{H} = 0, \quad \frac{1}{c} \frac{\partial \mathcal{H}}{\partial t} + \nabla \times \mathcal{E} = 0 \quad (6)$$

$$\nabla \cdot \mathcal{E} = 0, \quad \nabla \cdot \mathcal{H} = 0 \quad (7)$$

Now consider the complex three-dimensional vector

$$\mathbf{X} = \mathcal{E} + i\mathcal{H} \quad (8)$$

It has the following interesting properties.

(a) For a plane electromagnetic wave, whose electric and magnetic vectors are perpendicular and equal (in magnitude), the Lorentz-invariant square of \mathbf{X} vanishes; i.e.,

$$(\mathcal{E} - i\mathcal{H})^2 = \mathcal{E}^2 - \mathcal{H}^2 - 2i\mathcal{E} \cdot \mathcal{H} = 0 \quad (9)$$

or

$$|\mathcal{E}| = |\mathcal{H}|, \quad \mathcal{E} \cdot \mathcal{H} = 0$$

The latter two are the two Lorentz-invariant properties of a plane electromagnetic wave.

(b) The energy density of the field can be expressed in terms of the rotation-invariant square of \mathbf{X} as

$$cP_4 = \frac{1}{8\pi} |\mathbf{X}|^2 = \frac{1}{8\pi} \langle \mathbf{X} | \mathbf{X} \rangle = \frac{\mathcal{E}^2 + \mathcal{H}^2}{8\pi} \quad (10)$$

where $|\mathbf{X}\rangle$ is the column vector

$$|\mathbf{X}\rangle = \begin{bmatrix} X_1 \\ X_2 \\ X_3 \end{bmatrix}$$

and $\langle \mathbf{X} | = [X_1^*, X_2^*, X_3^*]$ is Hermitian conjugate row vector of $|\mathbf{X}\rangle$.

(c) The momentum density of the field has the form

$$P_i = \frac{1}{8\pi c} \langle \mathbf{X} | K_i | \mathbf{X} \rangle \quad (11)$$

where the Hermitian 3×3 matrices K_i were defined by

$$K_j = \begin{bmatrix} 0 & -i\delta_{j3} & i\delta_{j2} \\ i\delta_{j3} & 0 & -i\delta_{j1} \\ -i\delta_{j2} & i\delta_{j1} & 0 \end{bmatrix} \quad (12)$$

where δ_{ij} is the usual Kronecker tensor with $\delta_{ij} = 1$ if $i = j$ and $\delta_{ij} = 0$ if $i \neq j$.

The two expressions of Eqs. (10) and (11) for energy and momentum densities, respectively, can be combined into a single equation,

$$cP_\mu = \frac{1}{8\pi} \langle \mathbf{X} | K_\mu | \mathbf{X} \rangle \quad (13)$$

where K_4 , corresponding to $\mu = 4$, is a 3×3 unit matrix. In order to illustrate the meaning of Eq. (13) we shall, as an example, work out the third component of Eq. (13). It is given by

$$\begin{aligned} cP_3 &= \frac{1}{8\pi} [X_1^*, X_2^*, X_3^*] \begin{bmatrix} 0 & -i & 0 \\ i & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} X_1 \\ X_2 \\ X_3 \end{bmatrix} \\ &= \frac{i}{8\pi} (X_1 X_2^* - X_1^* X_2) = \frac{1}{4\pi} (\mathcal{E}_1 \mathcal{H}_2 \\ &\quad - \mathcal{E}_2 \mathcal{H}_1) = \frac{1}{4\pi} (\mathcal{E} \times \mathcal{H})_3 \end{aligned}$$

which verifies the statement in (c) above.

(d) The momentum and energy densities of the field are conserved; i.e.,

$$\frac{\partial cP_\mu}{\partial x_\mu} = \frac{\partial P_4}{\partial t} + c \nabla \cdot \mathbf{P} = 0 \quad (14)$$

provided the complex vector $|\mathbf{X}\rangle$ satisfies the equation

$$K_\mu \frac{\partial}{\partial x_\mu} |\mathbf{X}\rangle = 0 \quad (15)$$

Equation (15) can also be written as

$$i \frac{\partial}{\partial t} |\mathbf{X}\rangle = -ic \mathbf{K} \cdot \nabla |\mathbf{X}\rangle \quad (16)$$

where, it is easy to see,

$$-i \mathbf{K} \cdot \nabla |\mathbf{X}\rangle = \nabla \times \mathbf{X} \quad (17)$$

Hence Eq. (16) is equivalent to Maxwell's equations [Eq. (6)]. Therefore, the conservation of energy and momentum density of the field is a consequence of Maxwell's equations or, conversely, if Maxwell's equations are satisfied, the vector P_μ is conserved.

We write Maxwell's equations in the form

$$i\hbar \frac{\partial}{\partial t} |\mathbf{X}\rangle = H |\mathbf{X}\rangle \quad (18)$$

where

$$\nabla \cdot \mathbf{X} = 0 \quad (19)$$

$$H = -ic\hbar \mathbf{K} \cdot \nabla = c \mathbf{K} \cdot \mathbf{p} \quad (20)$$

has the dimensions of energy. The momentum operator \mathbf{p} is defined as

$$\mathbf{p} = -i\hbar \nabla$$

The complex vector $|\mathbf{X}\rangle$ has the physical dimensions of the square root of energy density. It will be more convenient to work with a complex vector $|\eta\rangle$, having the dimensions of the square root of (volume)⁻¹, defined by

$$|\mathbf{X}\rangle = \sqrt{(8\pi E)} |\eta\rangle \quad (21)$$

and satisfying the condition of normalization,

$$\int \langle \eta | \eta \rangle d^3x = 1 \quad (22)$$

where E is the energy of the photon. With these premises, the wave equation (or Schrödinger's equation) of the photon becomes

$$i\hbar \frac{\partial}{\partial t} |\eta\rangle = H |\eta\rangle \quad (23)$$

$$\nabla \cdot \eta = 0 \quad (24)$$

The formalism contained in Eqs. (23) and (24), with the definitions of H by Eq. (20), will be shown to be consistent and compatible with the observed facts $E = \hbar\nu$ and $\lambda = \hbar/p$ of the photon.

The Fourier series expansion of the wave function can be given as

$$|\eta\rangle = \frac{1}{\sqrt{V}} \sum_k e^{i\mathbf{k} \cdot \mathbf{r}} |\phi_k\rangle \quad (25)$$

where summation refers to all three components of the \mathbf{k} vector and is over all the k , defined according to

$$k_1 = \frac{2\pi}{L} n_1, \quad k_2 = \frac{2\pi}{L} n_2, \quad k_3 = \frac{2\pi}{L} n_3 \quad (26)$$

The complex vectors $|\phi_k(t)\rangle$ are functions of the wave number and of time t . By substituting the function $|\eta\rangle$ given by Eq. (25), in Eqs. (23) and (24), we obtain

$$i\hbar \frac{\partial}{\partial t} |\phi_k\rangle = H |\phi_k\rangle \quad (27)$$

$$\mathbf{k} \cdot \boldsymbol{\phi}_k = 0 \quad (28)$$

where n_1, n_2, n_3 are integral numbers specifying wave number vector \mathbf{k} in a plane wave $\exp(i\mathbf{k} \cdot \mathbf{r})$, and

$$H = \hbar c \mathbf{k} \cdot \mathbf{K}$$

so the operator p acts on $|\phi_k\rangle$ according to

$$p|\phi_k\rangle = \hbar \mathbf{k} |\phi_k\rangle \quad (29)$$

Thus the vector $\hbar \mathbf{k}$ can be interpreted as the eigenvalue of the operator p corresponding to the eigenvector $|\phi_k\rangle$.

In order to find the eigenvalues of the operator H , we may look for the stationary-state solutions of Eq. (27). We assume that the vector $|\phi_k(t)\rangle$ is periodic in time and that in accordance with the relation $E = \hbar\nu$, we write

$$|\phi_k(t)\rangle = |a_k\rangle e^{-i(\hbar\nu)t} \quad (30)$$

This form of the wave refers to a stationary state. The first expression of Eq. (27) now becomes

$$E|a_k\rangle = H|a_k\rangle \quad (31)$$

In matrix form, it can be written as

$$\begin{bmatrix} E & icp_3 & -icp_2 \\ -icp_3 & E & icp_1 \\ icp_2 & -icp_1 & E \end{bmatrix} \begin{bmatrix} a_{k1} \\ a_{k2} \\ a_{k3} \end{bmatrix} = 0 \quad (32)$$

Solutions for Eq. (32) require the vanishing of the determinant of $(E - H)$. In Eq. (32) the vector a_k is, of course, subject to the condition

$$\mathbf{k} \cdot \mathbf{a}_k = 0$$

By taking the determinant of $(E - H)$ we obtain

$$E(E^2 - c^2 p^2) = 0$$

The eigenvalue $E = 0$ implies [as seen from Eq. (32)] that the vectors a_k and p are parallel, which is not consistent with $p \cdot a_k = 0$. Hence the solution $E = 0$ must be discarded by the condition of transversality of the wave. The remaining two solutions are

$$E = cp = \hbar k = \hbar\nu$$

$$E = -cp = -\hbar k = -\hbar\nu$$

The negative sign in the second case is not to be understood as referring to a negative energy state. It has to do with the spin degree of freedom of the photon. This can be seen from writing the wave equation for negative energy,

$$(\mathbf{c} \cdot \mathbf{p}) |\eta\rangle = -E |\eta\rangle$$

and taking complex conjugate of both sides in the form

$$\mathbf{c} \cdot \mathbf{p} |\eta^*\rangle = E |\eta^*\rangle.$$

Thus both energy states are positive and they refer respectively to the energy of a right circularly or left circularly polarized photon, with spin parallel or antiparallel to \mathbf{k} . The two states can be represented by $|\eta\rangle$ and $|\eta^*\rangle$.

We have seen that at a given time, the value of the wave function can be obtained by a certain superposition of plane waves. In analogy to the classical definition of the intensity of a wave we shall look upon the real quantity

$$P = \langle \eta | \eta \rangle$$

as a probability density in the sense that EP is the energy density over a region that is large compared to the wavelength of the photon. The probability depends, of course, on the value of the wave function at the particular point. We can choose $|\eta\rangle$ in such a way that it differs from zero only over a region Ω of the dimensions of the wavelength of the photon. It shall be composed of monochromatic plane waves that interfere destructively outside the region Ω ; the frequencies and wavenumbers of these waves differ very little from each other inside the region Ω . In this particular region, the waves interfere constructively and the wave function $|\eta\rangle$ assumes large values there. This is equivalent to a localization of the photon. If this localization process is described in accordance with uncertainty relations between the dynamical variables of the photon, then the region in question is a wave packet. These arguments are, of course, valid also for mass particles.

The amplitudes of the waves that constitute a packet are different from zero only in the packet. These wave amplitudes constitute a wave group and have a group velocity that differs from the velocity of a single plane wave ("phase velocity").

In classical mechanics, the specification of positions and velocities of a dynamical system at each time is sufficient for a complete determination of its state. The basic concepts of classical theory (mechanics) consist of the material point, the force of interaction between material points (potential energy), and the inertial system (= the Cartesian coordinate system, the time coordinate or all reference frames in uniform relative motion). When the electromagnetic field is included, classical physics gains the concept of field, a region of space at every point of which a material particle can experience a force. Thus a field has an energy and momentum content. Special relativity brings into the structure of the inertial system the constancy of the velocity of light. In this theory, one cannot preserve the concepts of action at a distance and potential energy and this in turn implies that the concept of the material point can be discarded and replaced by the field concept.

A more profound change in our concepts of space and time came with the discovery of general relativity (the principle of general covariance,

invariance of the laws of nature with respect to all coordinate transformations, not necessarily in uniform relative motion). According to this theory, inertial systems need not be qualified as the only group of systems for the formulation of physical laws. The "space" represented by the inertial group (the Lorentz group), and considered as a part of the physical reality, can have only a limited meaning. The inertial group is used to determine the behavior of mass points in space and time, without itself being influenced by mass points. Therefore, according to special relativity, the inertial group occupies an absolute position in the description of physical phenomena.

In general relativity, however, the inertial group does not have this privileged position; in general relativity, it has been integrated into the field and has, therefore, been deprived of its "absoluteness." It is the field which has an independent meaning, and it depends on four parameters (the coordinates). The space aspect of matter itself is described by the field. The inertial character of real things must be derivable from a field; we do not try to fit a field to a given inertial group or to a mechanical system without considering that it will not change or influence the inertial system. In short, the mechanics of a system should be derivable from a field.

In quantum theory, we retain the inertial frame and the action-at-a-distance concepts, but it is no longer true that a state is completely defined by the initial conditions of the dynamical system.

According to quantum theory a "small system"—i.e., a system that can change its state (energy, momentum, position, angular momentum, and so on) by an act of observation—cannot be observed with the greatest possible amount of detail. The behavior of nature in the micro system is such that there exists a limitation or a lower limit to the power of observation. This limitation on the observability of a dynamical system implies a restriction on the data that can be assigned to the state of the physical system. Both classical and relativistic mechanics permit a definite distinction between observer and observed. This is essentially a complete fulfillment of the principle of causality in a deterministic sense. Accordingly, the interaction between observed and observer, arising in the act of observation, can be made infinitely small. For this reason it is meaningful, in classical mechanics, to say that the state of a dynamical system can be defined in its entirety with no limitation on the detail of the data. The continuous nature of things, for example the absorption of a wave by an electron, will allow enough time to measure its position and momentum rapidly before it absorbs sufficient energy from the incident wave to change its state abruptly.

The quantum mechanical point of view, at the expense of some loss of exact information on the dynamical system, recognized the impossibility of controlling the interaction between observer and observed. In the act of observation large changes in the state of the system being observed must be taking place. It is, therefore,

not possible to assign simultaneous "initial values" to canonically conjugate variables referring to the same degree of freedom of the dynamical system, e.g., x and p_x the coordinate and the corresponding linear momentum. This proposal of quantum mechanics can only be reconciled with a statistical or probabilistic approach to the description of physical reality. The complete determinism of classical theory is replaced by an indeterministic description, the extent of indeterminism being determined by the size of the universal constant h , Planck's constant. In classical mechanics, a cause causes another definite cause. In quantum mechanics, a cause can only produce a statistical trend to a given cause. This in turn can be regarded as a tendency towards some effect. The mode of the statistical tendency can be incorporated into a fundamental principle of nature, first enunciated by Heisenberg as the "principle of uncertainty" in the origination of physical events (see HEISENBERG UNCERTAINTY PRINCIPLE).

According to the principle of uncertainty, the position of an electron can be defined within a certain accuracy Δx at the time t , where Δx is a possible spread in the location of the electron; i.e., the electron can be seen within a region of the dimensions of Δx . The size of this region will depend on the spread of its momentum caused by the act of observation. In modern theory it is believed that the only description consistent with the principle of uncertainty is to represent the spread Δx as a "wave packet," the particle under observation being the wave itself. A wave packet has the properties of waves whose amplitudes are different from zero only in a limited region of space-time.

A dynamical system, having a well-defined single path in classical mechanics, is described in quantum mechanics by a wave packet containing coordinates and momenta with approximate numerical values that are restricted by the uncertainty principle. The size of the packet will increase with time; i.e., a wave packet can spread out and decay. If we succeed in obtaining, during our act of observation, a wave packet that can be located in a region smaller than Δx , then the location of the electron is sharper than ever. The latter result can only be approached as a result of large interaction between the electron and observer, resulting in a spread of the momentum of the wave packet much larger than the spread in its position. This uncertainty must be regarded as a fundamental property of a small object (electron) and, indeed, as its definition. The mathematical statement of the principle of uncertainty is contained in the relation

$$\Delta x \Delta p_x \geq h \quad (33)$$

The same kind of uncertainties will, of course, prevail for all other canonically conjugate dynamical variables of the wave packet—for example, the spread in its energy—and the corresponding spread in the time will satisfy the uncertainty relation

$$\Delta t \Delta E \geq h \quad (34)$$

The question now arises: what is it that the act of observation does to a dynamical system? What kind of a statement is the observer going to make following the observation of the dynamical system? An observable in quantum mechanics—such as energy, momentum, etc.—is, first of all, represented by a linear Hermitian operator. Let α be such an operator, with eigenstates $|\alpha'\rangle$ corresponding to its eigenvalue α' . If the state of the dynamical system during the act of measurement happens to be the eigenstate of α , then the eigenvalue α' is the result of the measurement. Whatever the state of the system prior to measurement was, the act of observation has caused it to jump to its eigenstate $|\alpha'\rangle$. A second measurement carried out in the state represented by $|\alpha'\rangle$ must give the same result. Therefore, any result of a measurement of an observable is one of its eigenvalues. The eigenvalues of a dynamical variable come into existence as a result of acts of measurement. Without the act of observation, we cannot talk of any state and consequently there exists no wave function prior to the process of measurement. Quantum mechanics is not concerned with the state and the corresponding possible values of a dynamical variable prior to observation. Quantum mechanics predicts the future from the present data

in accordance with the principle of uncertainty. In general, every experiment aimed at a determination of some numerical quantity causes a loss of information in some other quantity, related to the former by uncertainty relations. The uncontrollable perturbation of the observed systems alters the value of the previously determined quantities, except when the corresponding linear Hermitian operators commute with one another, i.e., the measurement of one is not affected by the measurement of the other.

R

RADAR

Radar is the name given to the use of electromagnetic energy for the detection and location of reflecting objects. It operates by transmitting an electromagnetic signal and comparing the echo reflected from the target with the transmitted signal.

The first demonstration of the basic radar effects was by Heinrich Hertz in his famous experiments in the late 1880's in which he verified Maxwell's electromagnetic theory. Hertz showed that short-wave radiation could be reflected from metallic and dielectric bodies. Although the basic principle of radar was embodied in Hertz's experiments, the practical development of radar had to wait more than 50 years for radio technology to advance sufficiently. It wasn't until the late 1930's that practical models of radars appeared. The rapid advance in radar technology during World War II was aided by the many significant contributions of physicists and other scientists pressed into the practical pursuit of a new technology important to the military. In addition to its military application, radar has been applied to the peace-time needs of air and ship navigation, air traffic control, rainfall observation, tornado detection, hurricane tracking, surveying, radar astronomy, and the familiar speed measuring meter of the highway police (see PROPAGATION OF ELECTROMAGNETIC WAVES).

The measurement of distance, or range, is probably the most distinctive feature of radar. Range is determined from the time taken by the transmitted signal to travel out to the target and back. The distances involved might be as short as a few feet or as long as interplanetary distances.

If the target is in motion relative to the radar, the echo signal will be shifted in frequency by the DOPPLER EFFECT and may be used as a direct measurement of the relative target velocity. A more important application of the doppler shift is to separate moving targets from stationary targets (clutter) by means of frequency filtering. This is the basis of MTI (moving target indication) radar.

Radar antennas are large compared to the wavelength so as to produce narrow, directive beams. The direction of the target may be inferred from the angle of arrival of the echo. Radar antenna technology has profited greatly from the theory and practice of optics. Both the lens and

the parabolic mirror have their counterpart in radar, and the analysis of antenna radiation patterns follows from diffraction theory developed for optics. The greater versatility of materials in the radar frequency region of the electromagnetic spectrum, however, offers more flexibility in implementing many of the principles of optics not practical in the visual portion of the spectrum.

The external appearance of a radar is dominated by its ANTENNA. Most radars use some form of parabolic reflector. The radar antenna can also be a fixed array of many small radiating elements (perhaps several thousand or more) operating in unison to produce the desired radiation characteristics. Array antennas have the advantage of greater flexibility and more rapid beam steering than mechanically steered reflector antennas because the beam movement can be accomplished by electrically changing the relative phase at each antenna element. High power can be radiated since a separate transmitter can be applied at each element. The flexibility and speed of an array antenna make it necessary in many instances to control its functions and analyze its output by automatic data processing equipment rather than with an operator using a grease pencil to mark the face of a cathode ray tube.

Radars are generally found within the microwave portion of the electromagnetic spectrum, typically from about 200 Mc (1.5 meters wavelength) to about 35,000 Mc (8.5 mm wavelength). These are not firm bounds. Many radars operate outside these limits. The famous British CH radar system of World War II which provided warning of air attack, operated in the high-frequency region of the spectrum in the vicinity of 25 Mc. Experimental radars have also been demonstrated in the millimeter wavelength region where small physical apertures are capable of narrow beam widths and good angular resolution. The radar principle has also been applied at optical frequencies with LASERS for the measurement of range and detection of small motions (using the Doppler effect).

The detection performance of a radar system is specified by the *radar equation* which states

$$P_{\text{rec}} = \frac{P_t G}{4\pi R^2} \times \sigma \times \frac{1}{4\pi R^2} \times A$$

$$\text{Received power} = \frac{P_t \times G \times \sigma \times A}{R^4}$$

Power Target Space Antenna
 density back- atten- collec-
 at a scatter uation ting
 distance cross on area
 section return
 path

where P_t is the transmitted power, G is the transmitting antenna gain, R is the range, σ is the backscatter cross section, and A is the effective receiving aperture of the antenna. The wavelength λ of the radar signal does not appear explicitly in this expression, but it can be introduced by the relationship between the gain and effective receiving area of an antenna which states $G = 4\pi A/\lambda^2$.

The detection capability and the measurement accuracy of a radar are ultimately limited by noise. The noise may be generated within the radar receiver itself, or it may be external and enter the receiver via the antenna along with the desired signal. External noise is generally small at microwave frequencies, but it can be a significant part of the overall noise if low-noise receiving devices such as the MASER and the parametric amplifier are used (see MEASUREMENTS, PRINCIPLES OF).

Since the effects of noise must be considered in statistical terms, the analysis and understanding of the basic properties of radar have benefited from the application of the mathematical theory of statistics. The statistical theory of hypothesis testing has been applied to the radar detection problem where it is necessary to determine which of two hypotheses is correct: the output of a radar receiver is due to (1) noise alone or (2) signal plus noise. One of the results is the quantitative specification of the signal-to-noise ratio required at the receiver for reliable detection. Also derived from hypothesis testing based on the likelihood ratio or a *posteriori* probability are concepts for ideal detection methods with which to compare the performance of practical receivers. The statistical theory of parameter estimation has also been applied with success to analyze the accuracy and theoretical limits of radar measurements.

Reliable detection of targets requires signal-to-noise power ratios of the order of 10 to 100 at the receiver, depending on the degree of error that can be tolerated in making the decision as to the presence or absence of a target. Even larger values are generally needed for the accurate measurement of target parameters. (These values may seem surprisingly high but, for comparison, the minimum signal-to-noise ratio of quality television signals is usually of the order of 10,000.)

The rms error δT in measuring the time delay to the target and back (the range measurement) can be expressed as

$$\delta T = \frac{1}{\beta \sqrt{2EN_0}}$$

where β is defined as the effective signal bandwidth, E is the total energy of the received

signal, and N_0 is the noise power per unit cycle of bandwidth assuming the noise has a uniform spectrum over the bandwidth of the receiver. The square of β is equal to $(2\pi)^2$ times the second central moment of the power spectrum normalized with respect to the signal energy. For a simple rectangular pulse, E/N_0 is approximately equal to the signal-to-noise (power) ratio. To obtain an accurate range measurement, E/N_0 and the signal bandwidth must be large. A similar expression applies to the accuracy of the measurement of Doppler frequency if the rms time delay error is replaced by the rms frequency error and the effective bandwidth is replaced by the effective time duration of the signal. Thus, the longer the signal duration and the greater the ratio E/N_0 , the more accurate is the Doppler frequency measurement. Likewise the angular measurement accuracy also depends on the ratio E/N_0 and the effective aperture size.

In addition to noise, radar can be limited by the presence of unwanted interfering echoes from large nearby objects such as the surface of the ground, trees, vegetation, sea waves, and weather. Although these "clutter" echoes may be troublesome in some applications, they are sometimes the echoes of interest as, for example, in ground mapping and meteorological applications.

Radar comes in many sizes and shapes. The smallest can be held in the hand and might radiate as little as a few milliwatts and be used to detect the movement of people at short range. The largest might radiate megawatts of average power and operate with antennas the size of a football field and would be used for the detection of space objects at ranges of many thousands of miles or more.

RADIATION BELTS

The first U.S. satellite Explorer 1 in 1958 carried Geiger counters designed by Van Allen of Iowa. This instrument discovered the high flux of energetic charged particles trapped in the

magnetic field of the earth now called the Van Allen radiation belt. We now know that this belt is made up of high-energy protons and electrons put into the magnetic field from several different sources. The particles travel in helical paths along field lines bouncing back and forth from one hemisphere to the other. The fact that the field lines converge towards the earth produces a force on the particle of $F = evB_{\perp}$ where B_{\perp} is the component of the magnetic field perpendicular to the field lines. This force pushes the particle out of the region of converging field and produces the bouncing motion. Without this bouncing motion, radiation belts would not exist. Other forces such as the centrifugal force on a particle moving along a curved field line make the particle drift in longitude around the earth. This combination of motions makes a roughly spherical belt of particles around the earth. The particles are not observed below about 500 km altitude. The fact that the earth's magnetic field is not symmetric but is weaker in the South Atlantic means the trapped particles are observed at lower altitudes there. The absence of trapped particles at low altitudes is clearly due to the presence of the atmosphere. The particles are lost very rapidly below this by coulomb scattering and energy loss to the thermal atmospheric atoms.

In 1959, Freden and White flew nuclear emulsions on an Atlas rocket, recovered them, and measured the tracks to show that the most energetic particles in the inner part of the radiation belt were protons with energies up to at least 700 MeV. This particle population stays constant for long periods of time with a maximum flux of about $10^4 \text{ cm}^{-2} \text{ sec}^{-1}$. We understand well how these high-energy protons are made. Very high-energy cosmic rays from space bombard the earth's atmosphere, collide with nitrogen or oxygen nuclei, and produce neutrons. Some of these neutrons emerge from the top of the atmosphere and, being radioactive, decay in space, producing protons and electrons. A quantitative study of these neutron-decay protons shows they have all the right properties to be the source of the observed protons from 10 MeV up.

The radiation belt extends out to about 10 earth radii and then stops abruptly. This outer edge is caused by the action of the sun on the earth. The solar corona is very hot and is unstable. Because of this, the sun continuously blows a wind of protons and electrons at the earth with a velocity of about 400 km/sec. This plasma pushes in the geomagnetic field until the solar wind pressure is balanced by $B^2/8\pi$, the pressure of the distorted geomagnetic field pushing outwards. Thus a boundary, called the magnetopause, exists between the solar environment and the geomagnetic field. Only inside the cavity, called the magnetosphere, occupied by the earth's field can trapped particles exist. Outside this cavity, a zone of energetic electrons exists, apparently made as a result of the solar wind hitting the magnetosphere and producing a turbulent region. These particles are not trapped.

The low energy trapped electrons found inside the magnetosphere have similar energies and flux to those outside, suggesting that the boundary is leaky and the electrons somehow diffuse in across the boundary.

We know that auroras are made mostly by energetic electrons striking the upper atmosphere. There is clearly a relationship between auroras and the trapped electrons found in the outer part of the radiation belt. They seem to be made by the same process (see AURORA AND AIRGLOW).

A large population of protons of about $10^6 \text{ cm}^{-2} \text{ sec}^{-1}$ is found in the outer part of the magnetosphere. They have energies of the order of 1 MeV. The protons have systematically higher energies closer to the earth as would be expected if they were drifting inwards and being accelerated by the increasing magnetic field as they go. A varying intensity solar wind can change the size of the magnetosphere, and as a result, a series of changes magnetically pump these particles inward to give the observed properties of the protons.

Clearly, all the processes operating to introduce particles into the radiation belt or all the ways in which particles are lost are not understood. All of the components of the trapped radiation have probably not even been found because we have not studied low-energy (less than 100 eV) particles well yet. One of the most important fields of study of the future will be to determine the types and occurrence rates of various natural magnetic disturbances at high altitudes which very likely play an important part in perturbing particle motion. A considerable amount has been learned about the natural Van Allen belt from studying charged particles artificially injected into the magnetosphere.

On seven occasions since 1958, artificial radiation belts have been made by the explosion of nuclear bombs at high altitude. The belt results from the β decay of the fission fragments made in the explosion. The decay produces several electrons per fission fragment with energies averaging about 1 MeV but extending up to 8 MeV. In 1958, three nuclear explosions in the South Atlantic, called the Argus experiment, were carried out to show that the earth's field could store charged particles. The planning for Argus was well along before Van Allen discovered the natural radiation belt. These explosions did make artificial radiation belts which were studied by the Explorer IV satellite.

In July 1962, the U.S. Starfish explosion of a 1.4-megaton bomb at 400 km over the central Pacific made a large artificial belt with electron fluxes up to $10^6 \text{ cm}^{-2} \text{ sec}^{-1}$. The satellites Injun I and III, Telstar I and Explorer XV followed the belt decay and showed that there are two different processes acting to remove the electrons. Below about 3000 km altitude, the electrons are lost mostly by coulomb scattering on the nuclei of the air atoms present, changing their direction of motion and diffusing down magnetic field lines into the atmosphere. An electron at 2000 km lives roughly a year before being lost this way.

At higher altitudes, the electrons are lost faster than this. Three Soviet high altitude explosions in the fall of 1962 produced artificial belts that decayed similarly to the Starfish belt. At 10,000 km altitude, the electron lifetime is just a few days. It seems probable that the electrons are lost here by interacting with electromagnetic waves, called whistlers. These waves are circularly polarized waves traveling along field lines. When the particle's gyration frequency resonates with the whistler wave frequency, the interaction can disturb the particle's motion and scatter it out of the trapping region.

We have some knowledge of radiation belts on other planets besides the earth. The Mariner space craft went within 40,000 km of Venus. It did not find a measurable planetary magnetic field or any trapped radiation belt. This does not necessarily mean that Venus does not have one at all. It does mean that if a magnetosphere filled with trapped particles exists on Venus, it must be quite small in size. Radio waves received from Jupiter, identified as synchrotron radiation from electrons gyrating around magnetic field lines, show that Jupiter has a trapped radiation belt. It must have considerably more high-energy trapped electrons than the earth's belt has because we haven't been able to observe synchrotron radiation from the natural Van Allen belt.

RADIATION CHEMISTRY

Radiation chemistry is the study of the chemical effects produced by the absorption of ionizing radiation. It includes chemical effects produced by the absorption of radiation from radiative nuclei (α , β , and γ rays), of high-energy charged particles (electrons, protons, recoil nuclei, etc.), and of electromagnetic radiation of short wavelength [x-rays with a wavelength less than about 100 Å and an energy greater than about 100 eV, for example]. Electromagnetic radiation of rather longer wavelength, in the ultraviolet and visible regions of the spectrum, may also initiate chemical reactions, though normally without producing ions as reactive intermediates; such reactions are the province of photochemistry. Reactions chemically similar to those caused by the absorption of ionizing radiation can be initiated by electric discharges; others, initiated in various ways, occur in the upper atmosphere.

Radiation chemistry originated with the observations by Röntgen (1895) and by Becquerel (1896) that led to the discovery of x-rays and of radioactivity, namely that photographic plates become fogged when placed near discharge tubes and uranium salts respectively. The subject was studied to only a limited extent until about 1942, when the advent of nuclear reactors and the increased interest in high-energy physics provided both the incentive and the means (in the

form of relatively cheap artificial radioactive isotopes and of large particle accelerators) for a more intensive study. In the following two decades, earlier work was consolidated and the basic mechanisms for radiation-induced action were established in outline, making possible an extremely rapid development of the subject since about 1960.

Absorption of any form of ionizing radiation by matter produces positive ions (A^+), electrons (e^-), and electronically excited atoms or molecules (A^*) distributed along the tracks of charged particles. The charged particles may be those which comprise the radiation (e.g., electrons or helium nuclei with fast electron or α -irradiation) or secondary particles produced by interactions of the primary radiation (e.g., fast secondary electrons formed by the absorption of x- or γ -rays, or fast protons produced by interaction of neutrons with hydrogenous materials). In addition, some of the electrons produced by ionization in the medium will have sufficient energy to produce further ionization and excitation, and will do so in slowing down to thermal energy (such electrons are known as δ rays). Except in gases, where the ions and excited molecules can diffuse apart quite readily, these primary species are initially concentrated within about 10 Å of the track of the ionizing particle. Heavy charged particles (protons and, particularly, helium nuclei and heavier particles) lose energy very rapidly in liquids and solids and leave a track densely populated with the primary species; radiations of this type are said to have a "high LET," where LET stands for linear energy transfer. In contrast, fast electrons and the secondary electrons produced by the absorption of x- and γ rays lose energy relatively slowly and form the primary species (which are the same as those produced by the heavier particles) in small groups containing, on an average, two or three ion pairs and about the same number of excited molecules. These groups (called *spurs*), with an initial diameter of ~ 20 Å, are separated by a relatively great distance ($\sim 10^3$ Å) from neighboring spurs along the same track, and the radiation responsible is said to have a "low LET." The initial localization of the ions and excited molecules in the track of a high-LET particle or in spurs produced by a low-LET particle causes spatial, or track, effects in radiation-induced reactions which are absent in photochemistry, where excited molecules are produced with an essentially uniform distribution in any plane at right angles to the direction of the beam of light. The excited molecules involved in radiation chemistry include excited states similar to those formed by the absorption of ultraviolet or visible light and also other states, formed by optically forbidden transitions or with more intrinsic energy, that are not produced photochemically.

Chemical changes in the irradiated material are brought about by breakdown or reaction of the ions and excited molecules and via free radicals formed by these primary species. Free radicals are chemically very reactive and are

produced in almost all materials upon irradiation. Their study has been greatly aided by the introduction of electron spin resonance (ESR) and pulsed radiation techniques. The sequence of events in many radiation-induced (radiolysis) reactions may be represented as:

The arrows represent dissociation of the intermediates, reaction between these species, and reaction with molecules of the substrate.

Quantitative studies in radiation chemistry are based either on the number of ions (N) formed in the irradiated medium or on the energy absorbed from the radiation. Ionization measurements in irradiated gases allow N to be estimated, and radiation yields in gases are best expressed as the ionic (or *ion-pair*) yield, M/N , where M is the number of molecules of product formed by radiation which produces N ion pairs. Reliable estimates of N are, at present, only available for gaseous systems, and for condensed materials it is usual to express the radiolysis yield as a G value (the number of molecules of product formed, or of starting material changed, per 100 eV of energy absorbed). Ionic yields and G values are related by $G = M/N \times 100/W$, where W (electron volts) is the mean energy required to form an ion pair in the material being irradiated. The determination of N , or of the energy absorbed, is termed "dosimetry" and may involve ionization measurements, calorimetry, measurement of the charge carried by a beam of charged particles of known energy, or measurement of a chemical change produced by irradiation [the oxidation of ferrous iron to ferric iron in 0.4 M sulfuric acid solution is often used (Fricke dosimeter)]. However, chemical dosimeters must first be calibrated against some absolute physical measurement.

Radiation-induced reactions have been studied in the gas, liquid and solid phases and in inorganic, organic, and biological systems. They have also been studied over a wide range of temperatures.

Most thoroughly studied of all radiation-induced reactions is the radiolysis of water and aqueous solutions, where the following have been

identified as the major products formed in the tracks or spurs: hydrogen (H_2), hydrogen peroxide (H_2O_2), hydrogen atoms ($H\cdot$), hydroxyl radicals ($\cdot OH$), and solvated, or hydrated, electrons (e_{aq}^-) (the formation of solvated elec-

trons is probably typical of polar liquids). These products are thought to be formed by the primary species, H_2O^+ , e^- , and H_2O^* , and, in the case of hydrogen and hydrogen peroxide, by $H\cdot$, $\cdot OH$, and e_{aq}^- . Relatively more hydrogen and hydrogen peroxide are formed in the track of a high-LET α -particle [$G(H_2) = 1.57$, $G(H_2O_2) = 1.45$] than in the spurs associated with a high-energy, low-LET, electron [$G(H_2) = 0.40$, $G(H_2O_2) = 0.80$] since the concentration of the precursors is greater in the track than in the spurs. However, relatively more of the other products ($H\cdot$, $\cdot OH$, and e_{aq}^-) escape from the spurs than from the α -particle track. These three species are free radicals and react very readily with substances present in solution, the hydroxyl radical generally producing oxidation, and the hydrogen atom and the solvated electron producing reduction, of the solute if the solution is free of air. Both the hydrogen atom and the solvated electron react rapidly with oxygen to give oxidizing species, so that oxidation reactions predominate when aerated aqueous solutions are irradiated.

Many organic materials have been irradiated and, making a very rough generalization, the products are those expected if the action of the radiation is to break the organic molecules randomly into two fragments (free radicals). The fragments then react together in pairs, again in a random fashion, either combining to form larger molecules or transferring an atom from one fragment to the other to give two stable molecules. The products from a hydrocarbon, for example, include hydrogen and hydrocarbons ranging in size from methane (CH_4) to compounds containing twice as many carbon atoms as the original compound; unsaturated materials, containing relatively less hydrogen than the original compound, will also be formed. Hexane,

$\text{CH}_3(\text{CH}_2)_4\text{CH}_3$, forms at least 16 products upon irradiation, of which the two most abundant are hydrogen ($G \approx 5.0$) and the dimeric C_{12} hydrocarbon ($G \approx 2.0$); the remaining products are formed with G values of 0.5 or less. More complex compounds may break preferentially (though generally not exclusively) at a particular point in the molecule; thus the carbon-iodine bond breaks most frequently when methyl iodide CH_3I , is irradiated. Some classes of compound can enter into chain reactions in which the reaction, once started, continues on its own. Typical of such substances are the unsaturated "monomers" which polymerize to produce polymers such as polymethyl methacrylate ("Lucite") and polyvinyl chloride (PVC). The chain reactions here are initiated by free radicals, and other means of producing free radicals besides irradiation bring about the same effect. G values for chain reactions may run from a few hundred to many thousands.

Aromatic compounds such as benzene are more resistant to radiation than most compounds lacking the "benzene" ring. Thus $G(\text{H}_2)$ from liquid benzene is only 0.036, and the total yield of radiolysis products does not exceed $G \approx 1$. In favorable instances, aromatic compounds can reduce the radiation damage in non-aromatic compounds mixed with them, energy absorbed by the second component being transferred in part to the "protecting" aromatic compound.

Apart from its intrinsic interest, the importance of radiation chemistry until the present time has rested largely upon its application to problems of reactor technology and its close relationship to radiation biology and radiation medicine. Recently, however, several industrial applications have been realized, e.g., the treatment of polyethylene to produce a higher-melting polymer and the synthesis of ethyl bromide via a radiation-induced chain reaction between ethylene and hydrogen bromide. Other commercial applications will undoubtedly follow, probably depending for their success on the special properties of high-energy radiation since it seems unlikely that high-energy radiation will ever be a very cheap means of introducing energy into a chemical system.

RADIATION, IONIZING, BASIC INTERACTIONS

Radiations of a large class, called ionizing, which interact with matter in its many forms and lead to a wide variety of "observed" or expressed effects have similar basic interaction pathways. Sources of ionizing radiations are varied and include radioactive isotopes, fission and fusion reactions, particle accelerators, and cosmic rays. Regardless of the source of any given radiation (applied to a given target), the basic interaction depends only upon the fundamental properties of the radiation itself.

Ionizing Radiations. The principal ionizing radiations are summarized in Table I. Although only the gamma or x-rays are electromagnetic in character and thus "radiations" in the classical sense, the distinction between "radiations" and ionizing "particles" is often not made (x-rays are distinguished from gamma rays only with respect to their origins; gamma rays result from nuclear interactions or decays; x-rays result from transitions of atomic or free electrons, produced artificially by bombarding metallic targets with energetic electrons). It is sometimes difficult to make a clear distinction between ionizing and nonionizing electromagnetic radiations, particularly in condensed phases. The ionization potential of *gaseous* elements i.e., the energy required for removal of the first electron, varies from 3.9 eV (Cs) to 24.6 eV (He). Comparable values are not well known for most complicated molecular systems or liquid- and solid-state systems, but they are probably in or near this general range. Although ultraviolet and even visible light can in special cases cause ionizations, the general assumption is that more energetic x- or gamma radiation is required to insure ionization. Hence the name "ionizing radiation" is reserved for electromagnetic radiation at least as energetic as x-rays and for charged particles of similar energies. Neutrons also lead to ionization, but for other reasons, described below. *Ionization* is, of course, not the sole interaction of high-energy

TABLE I

Name	Symbol	Location in Atom	Relative Rest Mass	Charge
Proton (H ¹) ⁺	<i>p</i>	Nucleus	1	+1
Neutron	<i>n</i>	Nucleus	1	0

Beta ⁻ (electron)	β^-	Emitted during decay processes	0.00055	-1
Beta ⁺ (positron)	β^+		0.00055	+1
Alpha (He ⁴) ⁺⁺	α		4	+2
Gamma* (photon)	γ	Emitted during decay processes	0.0	0

* X-rays of equal energy are identical, but of extranuclear origin.

particles and radiations with matter. The *excitation* of atomic electrons into higher-energy states always accompanies ionization.

Basic Action. The fundamental processes leading to ionization differ for charged particles, electromagnetic radiations, and neutrons.

Charged Particles. Fast charged particles are produced in radioactive decay processes, particle accelerators, nuclear reactions, and extraterrestrial sources. They undergo *coulombic* and *nuclear* interactions. The latter are far less probable and are discussed in other parts of this encyclopaedia (see NUCLEAR REACTIONS). There are two principal means whereby charged particles can lose energy by coulomb interaction: radiative loss and direct ionization. The probability of radiative energy loss (BREMSSTRAHLUNG) is roughly proportional to

$$\frac{z^2 Z^2 T}{M_0^2}$$

where *z* is the particle charge in units of the electron charge *e*, *Z* is the atomic number of the target material, *T* is the particle kinetic energy,

and *M₀* is the rest mass of the particle. The ratio of energy lost by bremsstrahlung to that by ionization can be approximated by

$$\left(\frac{m_0}{M_0}\right)^2 \frac{ZT}{1600 m_0 c^2}$$

in which *m₀* is the rest mass of the electron and *c²* is the speed of light squared, or 931 MeV per atomic mass unit. Electrons in the 10-MeV region lose about half of their energy by bremsstrahlung (in high-*Z* material), whereas heavier charged particles lose nearly all of their energy by ionization.

Loss of energy by ionization results when the particle undergoes coulomb collision with the *electrons* of the target. From the ratio of total energy lost to the number of ion pairs produced in cloud chambers (see Fig. 1), it has been estimated that approximately 100 eV are dissipated in each *primary ionization event* and that each event results in the production of, on the average, three ion pairs, each consisting of a free electron and a positive ion. If a resulting electron carries

IONIZATION BY DELTA RAYS

FIG. 1. Schematic drawing of a cloud-chamber photograph of the track of an ionizing particle, illustrating that ion pairs (illustrated by small circles) occur in clusters. Spurs indicated by arrows are ionizations due to *delta rays*. The arbitrary identification of the *track core* is also indicated.

more than a certain amount (usually considered to be about 100 eV) of kinetic energy, it is called a *delta ray*, because it is capable of further ionizations. "Delta ray" and "track core" ionizations are depicted in Fig. 1. The experimentally determined energy required to produce each *observed* ion pair lies in the range of 20 to 40 eV per ion pair for gases. A figure in the neighborhood of 30 eV per ion pair is commonly assumed for condensed phases of matter. This value is called "*W*" and is generally slightly different for electrons and heavy particles in the same material.

On the basis of coulomb scattering theory, it is possible to calculate the energy loss per unit path length ($-dT/dx$) for charged particles. For electrons and positrons the theory is complicated by the quantum mechanical effects of spin, identity, and relativity. In general, the *total* expectation energy loss per unit path length (also termed *mass stopping power* when path length is expressed in grams per square centimeter) for electrons and positrons can be expressed by

$$-\frac{dT}{dx} = \frac{2\pi e^4}{m_0 V^2} NZ \left\{ \ln \left[\frac{m_0 V^2 T}{2I^2(1 - \beta^2)} \right] - \beta^2 \right\}$$

in which V is the particle velocity, β is V/c , N is the number of atoms per unit mass, and I is the geometric mean ionization and excitation energy of the atoms of the target material. Classical theory is more adequate in describing the loss of energy by heavy charged particles, and the mass stopping power is determined from

$$-\frac{dT}{dx} = \frac{4\pi e^4 z^2}{m_0 V^2} NB$$

where B is called the *stopping number* and assumes various forms, some examples of which are

$$B = Z \ln \frac{2m_0 V^2}{I}$$

for nonrelativistic particles in material of low Z ;

$$B = Z \left[\ln \frac{2m_0 V^2}{I} - \ln(1 - \beta^2) - \beta^2 \right]$$

for relativistic particles in materials of low Z ; and

$$B = Z \left[\ln \frac{2m_0 V^2}{I} - \ln(1 - \beta^2) - \beta^2 - \frac{C_K}{Z} \right]$$

for relativistic particles in material of high Z , in which C_K is a term which corrects for the relative unavailability of K electrons for coulomb interactions. Corrections for L and M electrons may be required for very high- Z material.

Instead of stopping power, the term *linear energy transfer* (LET) is frequently used. The two quantities are not strictly interconvertible, according to a recent decision by the international committee on radiation units (see *National Bureau of Standards (U.S.) Handbook 84*). Mass stopping power should be used only in the sense

described above, whereas LET should be used only for energy lost by the particle within a specified distance of the track core. (Stopping power is usually expressed in units of million electron volts per gram per square centimeter, and LET in units of kiloelectron volts per micron.) These are both measures of linear *density of ionization* in the target material.

From the above equations, it is possible to derive range-energy relationships for charged particles by simple integration. Theoretical and experimental range-energy curves are now available in the literature for nearly all charged particles.

Electromagnetic Radiation (X, gamma). For fast, charged particles interacting with matter we had, above, relations of the form

$$-\frac{dT}{dx} \propto \frac{(\text{charge})^2}{(\text{velocity})^2}$$

If it were permissible to extend this idea to electromagnetic radiation, one might expect photons with no charge (and with the velocity of light) not to ionize at all. They indeed do ionize sparsely though for different reasons. The three principal mechanisms of interaction can be summarized as follows:

(1) Photoelectric effect. Low-energy photons can give up all their energy to a bound electron, forming an ion pair and disappearing in the process. (Generally unimportant above 1 MeV.)

(2) Compton scattering. For medium-energy photons (0.5 to 5 MeV), this elastic collision process predominates, leading to ejection of a recoil electron plus the partially degraded (longer-wavelength) photon.

(3) Pair production. Photons of highest energy most often interact by forming an electron-positron pair in the field of a nucleus and disappearing in the process. The absolute energy threshold for this process is the rest mass energy of the pair: 1.02 MeV.

The net result of all three processes is the formation of (charged) ion pairs and in particular of electrons having energies ranging up to the photon energy but on the average only a fraction of this maximum. The discussion on charged particles thus applies to x- or gamma-ray action also. Each of these processes will now be considered in more detail.

In the *photoelectric process*, the photon collides directly with an atomic electron, imparting kinetic energy

$$T = h\nu - B_e$$

where B_e is the atomic binding energy of the electron and $h\nu$ is the photon energy. For a considerable range of photon energies and target material Z 's, the probability of this process is approximately dependent upon the fourth power of Z and the inverse third power of the photon energy. There are, however, very specific energies at which photoelectric absorption is very probable ("absorption edges"), due to nearness of the photon energy to the binding energy of a

specific electron (K, L, M, etc.). The probability per unit thickness of absorber of a photon undergoing photoelectric absorption is denoted by τ . An initial photon intensity I_0 is reduced by this process to an intensity I_x after traversing a thickness of material, x , according to the relation

$$I_x/I_0 = e^{-\tau x}$$

The *Compton process* differs from the photoelectric process in two important ways: the photon usually loses less than all of its energy to the electron with which it collides, giving rise to a lower-energy scattered photon, and the process may occur with a free or loosely bound electron. Momentum and energy are conserved according to the laws of classical mechanics, and the energetics can be described by

$$h\nu = h\nu' + (m - m_0)c^2$$

where $h\nu'$ is the energy of the secondary photon, and $(m - m_0)c^2$ is the kinetic energy of the recoil electron (expressed in terms of the relativistic mass increase). At high photon energies, the collision probabilities are governed by the laws of quantum mechanics. Photons are lost by the Compton process according to the relation

$$I_x/I_0 = e^{-\sigma x}$$

where σ is the absorption probability per unit thickness.

If the energy of the photon is greater than two electron masses (1.02 MeV), there is a finite probability that it will interact with the nuclear field giving rise to electron-positron *pair production*. In pair production, energy is conserved according to

$$h\nu - 2m_0c^2 = T_+ + T_-$$

where T_+ and T_- are the positron and electron kinetic energies, respectively. The positive electron is ultimately annihilated by a negative electron, and the masses of both are converted into photons with energies distributed about 0.51 MeV (one electron mass each). Very high-energy electron-positron pairs may, in turn, produce further photons by bremsstrahlung, initiating a sequence of photon-electron-photon, etc., interactions, known as a *cascade*. (If the photon energy is greater than four electron masses, pair production may occur in the field of an electron, under which condition the original electron is set in motion, and the process is called "triplet production.") The probability of pair production increases very rapidly with increasing photon energy above 1.02 MeV and increases as Z^2 , the square of the atomic number of the target material. The absorption probability per unit thickness is denoted by κ , so that high-energy photons are absorbed according to

$$I_x/I_0 = e^{-\kappa x}$$

It is usually desirable to know the *total* photon absorption per unit thickness of a given material,

so one simply states

$$I_x/I_0 = e^{-\mu x}$$

where

$$\mu = \tau + \sigma + \kappa.$$

μ is called the "total linear absorption coefficient" and is expressed in units reciprocal to those in which x is measured.

Neutrons. Because of their lack of charge, neutrons do not interact electrostatically either with orbital electrons or with nuclei. They do interact with nuclei, however, in various other ways.

Fast neutrons (up to a few MeV) lose energy primarily by elastic collisions with other nuclei. From considerations of momentum transfer, this process is most efficient for target nuclei of about the same mass (i.e., protons in hydrogenous materials), though other light nuclei are also effective. On the *average*, about half the initial neutron kinetic energy is transferred to the protons, so that fast-neutron bombardment looks (to a hydrogenous material) like bombardment with fast protons of half the neutron energy. In addition to such simple collision processes, fast neutrons also induce nuclear reactions in certain elements, leading to emission of particles or photons with their previously described interactions.

After about 20 collisions, neutrons are no longer sufficiently energetic to eject recoil protons but have become "thermalized," i.e., they act (for a short time) like a gas in thermal equilibrium with its surroundings (energies of about 1/40 eV).

When a neutron has become thermalized and wanders into a nucleus, it is quite often captured, momentarily yielding an excited isotope of the original nucleus. Nuclei usually lose their excitation by emission of particles or characteristic gamma rays. Thus, even an uncharged slow neutron gives rise to the release of ionizing radiation inside a material being irradiated. In living tissue, slow neutrons commonly are captured by H^1 nuclei with emission of an energetic gamma ray, and by N^{14} nuclei with emission of an energetic proton.

Associated or Post-ionization Events. Subsequent to the primary and secondary molecular ionizations (and excitations), a number of events can occur that depend rather strongly on the form of the target material, including

(1) dissociation of molecules and formation of free radicals (species with unpaired electrons, hence great chemical reactivity, e.g., in water, H , OH , HO_2);

(2) recombination of ions and radicals, leading to no net change;

(3) dispersion of energetic ions and radicals, and reaction with other species present or with each other;

(4) nondiffusion migration of electronic excitation to energy "sinks," e.g., in macromolecules or crystals; and

(5) eventual degradation of the excess ab-

sorbed energy to heat (insignificant from the standpoint of effects).

For many systems the basic interactions must be considered only the initiators of a complex sequence of later events.

Comparison of the Radiations. Diverse electromagnetic and particulate radiations thus have in common as their basic interaction (or closely following upon it) the production of molecular ionizations (and excitations, dissociations, free radicals) inside target matter. They differ in the *geometry* of these events (especially in LET), a difference that leads to wide variations in range or penetrating ability and, thus, in the subsequent reactions leading to the final expression of the radiation effect.

The slower, more highly charged, heavy particles (such as alphas) travel in straight-line tracks ionizing densely along the track and exhibiting discrete ranges characteristic of the particle energy. Lighter, less highly charged particles such as electrons have their tracks more easily deflected and therefore have less precisely specified ranges in matter (although they have a maximum range). With a lower ionization density, however, they travel much farther than heavy charged particles of the same energy. Gamma or x-rays interact causing release of electrons in matter but at widely spaced intervals and in a random fashion; they have a still lower ionization density (LET) and much longer "range." (Since the resultant of all their absorption processes is a roughly exponential attenuation in matter, their "range" must be described in terms of a parameter such as "half thickness," x_1 , the thickness of material that reduces incident intensity to 50 per cent. The relation $x_1 = 0.693/\mu$ is seen to follow from the above equation for total photon absorption.) X-ray interaction has been likened to a "shotgun" effect in contrast to the "rifle" effect from incident heavy charged particles. Neutrons, which only interact with nuclei, may have either high or low LET. Their penetration in matter is great though difficult to specify well except in terms of specific materials. For much of their path, *fast* neutrons also are attenuated roughly exponentially.

The approximate range r or half thickness x_1 is given in Table 2 for several 1-MeV radiations in water.

TABLE 2

$\alpha(r)$ (cm)	$\beta-(\max r)$ (cm)	$\gamma(x_1)$ (cm)	Neutrons (x_1) (cm)
0.0007	0.4	10	5-10

Finally, a variety of conventional particle and wave interactions (such as reflection, transmission, and refraction) are also experienced by the above radiations. Moreover, many other more-or-less-ionizing radiations have been omitted from this discussion, including mesons, hyperons, heavy cosmic particles, large fission and

spallation products, and anti-particles. Their relative interactions can be quite well predicted from their composition, charge, and velocity, and the above considerations.

RADIATION, THERMAL

The term thermal radiation refers to the electromagnetic energy that all substances radiate, by transformation of their thermal energy. If a body lacks a source of replenishment for the thermal energy thus transformed, it will radiate away all of its available energy, and its temperature will approach absolute zero. As long as the temperature remains above approximately 500°C, some of the thermal radiation will lie in the visible spectrum. At lower temperatures, the energy lies at wavelengths too long to be seen.

The discovery that radiation existed outside the visible spectral region was made by Sir William Herschel in 1800. He formed a prismatic solar spectrum on a table top in a dark room and found that the temperature, as indicated by a sensitive thermometer, continued to increase beyond the red end of the spectrum.

Sources other than the sun were also studied. One that is of fundamental importance is an isothermal enclosure, or hohlraum, with a small hole for viewing the radiation escaping from the interior. Kirchhoff had proved, from the second law of thermodynamics, that the flux and the spectral distribution of the radiation are the same in all such enclosures at a given temperature, irrespective of the materials composing them. A related fact, known as Kirchhoff's law, is that the ratio of radiant emittance to absorptance is the same for all surfaces at the same temperature. (The radiant emittance of a surface is the integrated power radiated in all directions per unit area of surface. Definitions of other radiometric quantities, symbols and units will be found in the references.) In accordance with this law, metallic surfaces, having high reflectance and hence low absorptance, also have a low radiant emittance. Hence, the inner surfaces of the double walls of a Dewar flask are silvered, to minimize radiant heat loss.

At a given temperature, the surface having maximum absorptance will also have maximum emittance of radiant energy. Since such a surface absorbs all incident energy, it appears black, and the radiation it emits is known as "black-body radiation". Like the pupil of the eye, an opening in the surface of a hollow body appears to be perfectly black (as long as there is no reflection back out) and the opening acts as a black-body radiator as well as absorber. No surface

FIG. 1. Fractional deviation of classical radiation equations from the Planck equation.

can have a larger radiant emittance than a blackbody, at a given temperature.

Toward the end of the nineteenth century, quantitative studies of the magnitude and spectral distribution of blackbody radiation were made (see INFRARED RADIATION for typical curves). Stefan had found experimentally in 1879 that the radiant emittance of a blackbody, integrated over all wavelengths, is proportional to the fourth power of the absolute temperature. And, in 1884, Boltzmann gave a theoretical derivation for what is now known as the Stefan-Boltzmann law: $W = \sigma T^4$. The value of the constant σ is 5.67×10^{-12} watts $\text{cm}^{-2} \text{deg}^{-4}$. In 1893, Wien derived a "displacement law," one of whose implications is that $\lambda_{\text{max}} T = 2898$, where λ_{max} is the wavelength (in microns) at which maximum radiance occurs for a blackbody at absolute temperature T .

In 1896, Wien derived the following distribution law for the spectral radiant emittance W_λ of a blackbody: $W_\lambda = c_1 \lambda^{-5} \exp(-c_2/\lambda T)$. This fits the experimental observations within 1 per cent, provided λT is less than 3100, i.e., $\lambda \leq \lambda_{\text{max}}$; but at larger values, the predicted values rapidly become too low (see Fig. 1). On the other hand, by applying the classical equipartition theorem of statistical mechanics to the radiation, Rayleigh and Jeans derived the following formula: $W_\lambda = (c_1/c_2)\lambda^{-4}T$. For $\lambda \geq 250\lambda_{\text{max}}$, the Rayleigh-Jeans equation matches the experimental data to 1 per cent, but it diverges, leading to the "ultraviolet catastrophe," as $\lambda \rightarrow 0$. It remained for Max Planck in 1900 to find an expression that is valid at all wavelengths and temperatures, namely: $W_\lambda = c_1 \lambda^{-5} / [\exp(c_2/\lambda T) - 1]$. c_1 and c_2 are known as the first and second radiation constants, respectively, and have the values $c_1 = 3.74 \times 10^{-12}$ watt cm^2 ; $c_2 = 1.44$ cm degree. Planck's theory leads to the following expressions for the radiation constants in terms of fundamental

physical quantities: $c_1 = 2\pi hc^2$; $c_2 = hc/k$, c being the velocity of light, and k Boltzmann's constant. The validity of these expressions has been experimentally justified.

Planck first developed this law empirically, and tried unsuccessfully to justify it on the basis of classical physics. He was forced to postulate that the elementary oscillators, of which a radiating body consists, did not have a continuous distribution of energy, but only quantized values. According to the "quantum hypothesis," the energy E that an oscillator may assume is given by $E = nh\nu$, where n is an integer, and the proportionality constant h (now known as Planck's constant) $= 6.62 \times 10^{-34}$ watt sec². Though forced to assume that the energies of the elementary oscillators, of which the radiator is composed, could take on only discrete values, Planck considered the emitted radiation to be propagated according to classical electromagnetic theory. The quantization of the radiant energy into photons was conceived by Einstein and used by him to explain the phenomena of photoelectricity. These quantum concepts were later extended by Bohr and Sommerfeld to explain atomic spectra and by Schrödinger, Heisenberg, Dirac, and others to develop quantum mechanics. Thus, they stand as one of the most important milestones in the history of theoretical physics.

Integration of Planck's equation leads to the Stefan-Boltzmann equation. Wien's laws and the Rayleigh-Jeans law may also be derived from Planck's law under appropriate conditions. For example, when dealing with photons whose energy $h\nu$ is sufficiently small compared to the thermal energy kT , the product λT is large enough so that the exponential in the denominator of Planck's law may be replaced by the first two terms of a series expansion. This leads to the Rayleigh-Jeans law.

FIG. 2. General blackbody radiation curve.

High-speed computers have been used to compile tables of spectral radiance and related functions for a blackbody over a broad range of wavelengths and temperatures. There are also several radiation calculators, or slide rules, that are convenient for engineering use. Some of these make use of the fact that a log-log plot of blackbody radiation vs wavelength has the same shape at all temperatures. The radiance curve for a given temperature blackbody may then be obtained by sliding the universal curve in such a way that its peak falls on the line corresponding to the Wien displacement law (see Fig. 2 in INFRARED RADIATION). It is convenient to remember that the peak radiance varies as T^5 ; that a quarter of the total power radiated lies between $\lambda = 0$ and $\lambda = \lambda_{\max}$ (see Fig. 2); and that this power, on the short-wavelength side of the peak of the radiation curve varies as $T^{6.4}$. At wavelengths less than λ_{\max} , the monochromatic radiance changes as T^n , where $n \approx 15000/\lambda T$. For an object at 1500°K, for example, observed through an optical pyrometer with a filter transmitting at 0.6μ , $n \approx 17$. This relatively high value of n is advantageous in reducing the temperature error resulting from uncertainty in the observed radiance or the emittance of a surface.

The ratio by which the surface radiation falls short of that of an ideal blackbody, is denoted as the surface's emissivity or emittance. Some authorities prefer to use "emissivity" as a material property characterizing an ideally pure and polished surface of the material, as distinguished from the properties of engineering samples. The emittance of some substances, though less than one, is essentially the same at all wavelengths. Such radiators are referred to as gray bodies. In most real substances, however, emittance varies

as a function of wavelength as well as temperature.

If one can make a reasonable estimate of the emittance of a surface, a measurement of its thermal emission will give its temperature. This is the basis of contactless, radiometric temperature measurement. Should the emittance be unknown, but assumed to be relatively constant, a temperature may be inferred from the shape of the spectral distribution curve. Other schemes have also been used to determine the temperature of surfaces of undetermined characteristics.

The *color temperature* of a body is that temperature of a blackbody which has the same ratio of radiances as the selective radiator in two spectral intervals. In general, the value of the color temperature depends on the choice of the two spectral intervals. However, if these wavelengths are in the visible region, the color temperature is relatively insensitive to the specific values chosen. The color temperature of a gray body equals its true temperature. When dealing with semitransparent materials such as glass in the near infrared, one speaks of volume emissivity, which in turn is related to the optical constants of the material.

In some solids, and especially in gases and flames, the emittance in some spectral regions is much larger than in others. Kirchhoff's law tells us that gases radiate well in the same spectral regions where they have strong absorption bands. One must bear in mind, however, that the shape of an absorption band changes and new "hot" bands may appear as the gas temperature rises, so emittance and absorptance must be equated at the same temperature. The thermal radiation from a cool, low-pressure gas, is resolvable into discrete emission lines, as explained by the

quantum theory. Increased temperature and pressure cause the lines to broaden as a result of molecular interactions and perturbations of the energy levels, and new lines also appear. As the optical path length increases, the emissivity of the gas approaches unity, at first at the line centers, where the absorptance is strongest, and then extending into the line wings. Eventually, when the gas density and thickness are great enough, as on the sun, the original line spectrum assumes the appearance of a blackbody distribution. A good example of this is seen when one compares two infrared emission spectra of earth's atmosphere—first looking overhead from a mountain top, and then along the horizon at a humid sea-coast. The latter spectrum's blackbody-like shape (from which, incidentally, the atmosphere's temperature may be inferred) contrasts strongly with the peaks and valleys of the former.

In strongly absorbing spectral regions, only a relatively thin layer of gas, nearest the viewer, contributes to the observed radiance, the radiation by the more distant molecules having been almost completely absorbed by the nearer molecules. For this reason, the Fraunhofer lines in the solar spectrum, occurring at strongly absorbing atomic wavelengths, originate in the cooler outer part of the sun and appear relatively dark.

In exceptional situations, it is possible to circumvent the consequences of Kirchhoff's law. The Doppler shifts, due to the relative motion of the earth and Mars, prevents the narrow line radiation by planetary H_2O from being reabsorbed by terrestrial water vapor. As a result, it has been possible to estimate the water vapor concentration on Mars (see DOPPLER EFFECT AND PLANETARY ATMOSPHERES).

The spectral emittance of gases is an important area of investigation, with respect to such topics as the heat budget of the earth; the composition of planetary atmospheres; and radiation by flames and rocket engines. The analysis of the gas radiation transfer in many of these applications is complicated by the fact that conditions are nonisothermal.

The Welsbach mantle (or the Coleman lantern) is an example of selective radiation in a solid; in this case, its efficiency as a source of visible light is enhanced by the high emittance in the visible, and low emittance in the near infrared, of the mixture of thorium and cerium oxide of which the source is composed. For some metals, the emittance varies as $\sqrt{T/\lambda}$, while in others it may vary in a more complicated way. In either case, the form of the spectral distribution curve differs from that of a blackbody, and the total emission will usually vary more nearly as T^5 than as T^4 . The emittance of a tungsten filament is approximately 0.45 in the visible spectrum, decreasing to less than 0.2 in the infrared. Its visible efficiency increases as its operating temperature increases.

By considering the equilibrium between incoming and outgoing radiation, one can show that the sum of the radiant absorptance a , reflectance r , and transmittance t , is unity. These quantities refer to monochromatic, hemispherical radiation

from the surface and do not take into account the way it is distributed geometrically. For an opaque surface, $a + r = 1$, and since by Kirchhoff's law $a = e$, the emittance, we have $e = 1 - r$. Errors may result if due account is not taken of angular and spectral factors in the application of this equation. Early studies of the angular distribution of radiation from surfaces led to the formulation of Lambert's law, i.e., $J_\theta = J_n \cos \theta$, where J_θ is the source intensity or radiant power per unit solid angle in a direction making an angle θ with the normal to the surface, and J_n is the intensity along the normal. A surface that obeys Lambert's law is said to be perfectly diffuse, like a sheet of blotting paper in the visible. Its radiance, N (intensity per unit of projected area of source), is constant and independent of θ . Integration over the hemisphere leads to the relationship $W = \pi N$. A truly black surface obeys Lambert's law exactly. Although the law is a useful approximation for many radiators and reflectors, there are numerous exceptions. The emissivity of clean, smooth surfaces of some materials has been studied from a basic theoretical viewpoint and related to their optical constants. The analysis, whose results agree generally with experimental determinations, indicates that for electrical conductors, the normal emissivity is quite low and increases with θ ; whereas insulators have relatively high normal emissivity, decreasing at large values of θ . Insulators, as well as metals covered with thick oxide films, behave approximately as diffuse radiators. In the case of many practical materials, however, the surfaces are either rough or chemically complex, and it is necessary to rely upon empirically determined emittances. Many substances, such as concrete, porcelain, and paper, have a higher absorptance for long- than for short-wave radiation. Many more data are needed on the spectral emittances of various materials under different conditions. In addition to their engineering uses in radiant heat transfer calculations, emittance and reflectance data are being used to deduce the chemical composition of the moon and planets.

Space vehicles absorb energy from the sun and lose it by radiation to space. By the application of coatings with suitable radiative characteristics, the internal temperature of a vehicle may be controlled with desired limits. The quantity a/e is often used to characterize such coatings. It refers to the ratio of the absorptance of solar radiation (approximated by a 6000°K blackbody) to the emittance at the temperature of the vehicle's surface. High-temperature emittances of many materials are being studied in connection with the design of ablative nose cones, and re-entry vehicles.

Although all objects are continuously emitting and absorbing thermal radiation, specially designed sources are available for particular applications. For industrial heating and drying, for example, there are numerous varieties of heaters and infrared lamps. The latter are similar to incandescent lamps used for lighting purposes, but designed for operation at lower temperatures,

FIG. 3. Schematic representation of a conical blackbody that can be used at high or low temperature.

with reduced visible output. In recent years, high-temperature lamps with quartz envelopes have been used increasingly for both heating and illumination. The clarity of the envelope is maintained, and the filament life prolonged, by incorporating a small amount of iodine within the tube. Tungsten that has evaporated onto the tube walls combines with the iodine vapor to form tungsten iodide. This is a gas which decomposes thermally when it comes in contact with the hot filament, thus replenishing the latter and liberating the iodine for use again.

For scientific purposes, such as calibrating a radiometer or spectrometer, a reproducible source of known characteristics is essential. Sources with characteristics approaching those of an ideal blackbody, have been built for operation from cryogenic temperatures to about 3000°K. Most of the commercially available blackbodies, which come with a variety of aperture sizes and in many configurations, use a conical cavity (Fig. 3), the interior walls of which are oxidized or blackened to decrease their reflectance. Electrical heating is most often used, in conjunction with a thermostatic controller. A number of authors have discussed the considerations involved in designing a blackbody, and it is possible to calculate how closely a given design approximates an ideal blackbody. It is sometimes necessary to have a black radiating surface whose area is impractical to obtain with a cavity-type body. Flat surfaces have been coated with "blacks" whose emittances are close to unity over a broad spectral range. These are generally not suitable for high-temperature use, however. Other methods that have been used to obtain high-emittance surfaces include: wedges or closely stacked razor blades viewed edge on, a telescoped cone pattern similar to that of a Fresnel lens impressed on a flat surface, a vortex

in a liquid or molten metal, etc. The National Bureau of Standards has calibrated some special tungsten filament lamps for use as spectral irradiance standards from about 0.3 to 2.6μ . Beyond 2.6μ , strong, but variable, atmospheric absorption becomes troublesome. When using infrared sources for quantitative thermal radiation measurements, one must make due allowance for the absorption at different infrared wavelengths by the CO_2 and water vapor in the atmosphere between the source and the instrument being calibrated.

For reasons of compactness and convenience, it is sometimes desirable to use non-blackbody sources of thermal radiation. Among the most common of these are the Nernst glower, which is a hollow rod approximately 25 mm long and 2 mm in diameter, made of a mixture of oxides of zirconium, yttrium, and thorium and the globar, a rod of bonded silicon carbide. These are most useful at the shorter infrared wavelengths. In the far infrared, mercury discharge tubes and other sources have been used. At long wavelengths, the power output of a thermal radiator increases almost linearly with temperature, as indicated by the Rayleigh-Jeans law, and inordinately high temperatures would be required for a significant increase in power. Nonthermal sources, in particular lasers, or other coherent radiators can generate much greater power, though limited to a narrow wavelength interval.

In order to study the properties of materials at very high temperatures without contamination, it is convenient to heat them by thermal radiation rather than convection. Solar furnaces have been used for this purpose, as well as arc-imaging furnaces, in which a specially designed high-intensity carbon arc replaces the sun as the source.

Thermal radiation can be detected by eye when the source temperature is sufficiently high. And

although its sensitivity is greatly reduced at longer wavelengths, the human eye has some sensitivity to radiation at wavelengths as long as 1.2μ . Some insects, such as moths, respond to thermal radiation at even longer wavelengths, and some snakes can detect the heat of a warm-blooded animal at an appreciable distance.

Many types of detectors have been developed for thermal radiation. In some of these, known as quantum detectors, the energy of the incident photon must exceed some lower limit, but its effects are very rapid. An example is the lead sulfide detector. In others, thermal radiation of any wavelength can be detected by virtue of its effect on some physical property of the detector. The response of the latter kind of detector is slower than that of the former. Among the thermal detectors are: metal and thermistor bolometers, in which the absorbed radiation causes a slight temperature rise and consequent change in the resistance of the detector; thermocouples and thermopiles in which the differential heating of two junctions of dissimilar materials generates an emf; the Golay cell or pneumatic detector, where the absorbed radiation heats a gas and distorts a reflecting optical element; the evaporograph in which the incident radiation causes differences in the rate of evaporation of a thin oil film and the resulting differences in thickness give rise to interferometric patterns. Numerous other physical mechanisms have been exploited for radiation detection. (The more usual infrared detectors are discussed under INFRARED RADIATION.)

For coverage of an extended field of view, mosaics of conventional detectors have been used, as well as electronic imaging tubes such as infrared vidicons and orthicons. Whether by such detectors or by raster-like scanning of a small elemental field of view, it is possible to study the temperature pattern of an extended source of thermal radiation. Thermography is such a process, in which the temperature gradients are displayed in visible form, e.g., on photographic film. When properly interpreted, the thermograph can be a valuable diagnostic aid to the physician. Industrial thermography, as applied, for example, to the nondestructive testing of integrated electronic circuit boards is useful for design purposes or for quality assurance. In interpreting the observed patterns, one must bear in mind that radiance variations may result from differences in either or both surface emittance and surface temperature from point to point. This fact is less troublesome in medical thermography because the emittance of the body is close to unity. In a similar way, the radiometry of lakes, rivers, and oceans by an instrument looking vertically down from an aircraft, takes advantage of the near-unity emissivity of water within the range of wavelengths to which the radiometer is sensitive. In the near infrared and visible, as well as in the microwave region, water is not quite so opaque as it is around 10μ . Microwave radiometry, therefore, can give information about the water temperature slightly (1 or 2 mm) below the surface, rather than at the surface itself. Microwaves

are less subject than infrared to atmospheric absorption and are better able to penetrate overcast and clouds.

Satellite observations of the thermal radiation of the oceans and continents are of meteorological value. A special radiometric spectrometer, currently under development, records the thermal radiation of atmospheric carbon dioxide in a series of narrow wavelength intervals centered around the strong 15μ absorption band. The varying emittances of the atmosphere in these wavelength regions permit one to deduce a vertical profile of the atmosphere's properties from the observed data.

RADIO ASTRONOMY

Radio astronomy is concerned with measurement of radio-frequency radiation emitted naturally by celestial objects. It began in 1932, with the discovery of radio emission from the galaxy by K. G. Jansky at the Bell Telephone Laboratories. Fourteen years later, the U.S. Army Signal Corps and the Hungarian scientist Z. Bay, working independently, succeeded in obtaining radar echoes from the moon—thereby launching the related field of *radar astronomy*. Most recently, F. T. Haddock and D. Walsh at the University of Michigan, and A. E. Lilley at Harvard, have pioneered in *space radio astronomy*—the use of rocket-borne or orbiting radio telescopes to detect low-frequency radio waves that cannot penetrate the terrestrial ionosphere.

Radio Telescopes. A radio telescope consists basically of one or more aerials and a radiometer. The chief factor taken into account in the design of these components is the frequency range within which observations are to be made, and this parameter in turn depends on the nature of the studies proposed for the telescope. Investigations at meter wavelengths are chiefly limited by confusion of adjacent radio sources, rather than by instrumental sensitivity. Therefore, the emphasis in designing telescopes for use at these frequencies has been on the attainment of high spatial resolution, and this requirement has generally led to the adoption of interferometers in preference to "single dish" or filled aperture antennas.

L. L. McCready, J. L. Pawsey and R. Payne-Scott at Sydney introduced the technique of interferometry to radio astronomy in 1946. They used the Lloyd's mirror principle, with the ocean surface as reflector, to measure the angular diameter and position of a localized source of solar radio emission.

Two-element interferometers have been employed for sky survey work at the Mullard Radio Astronomy Observatory; others, notably those at Jodrell Bank, Owens Valley and Nançay, have yielded basic data on the brightness distributions of individual sources by means of variable baseline interferometry. As greater resolution becomes necessary to pursue current lines of inquiry at centimeter wavelengths, the two-element inter-

ferometer will become popular at those frequencies as well. Indeed, such an instrument, comprising two precisely figured 85-foot paraboloids, was completed in the summer of 1964 at the National Radio Astronomy Observatory, Green Bank. The simple interferometer has a *fan beam*, i.e., its high resolution is limited to one coordinate. Symmetrical or *pencil beams* have been synthesized at meter wavelengths with two-dimensional arrays of interferometer elements such as the *Mills Cross* developed at Sydney. However, the need for better resolution has already led to the construction of such arrays with characteristic dimensions on the order of a mile. The large number of individual aerials required in these projects raises many problems, not the least of which is cost. *Aperture synthesis*, an alternative approach introduced by M. Ryle and A. Hewish at Cambridge, involves the use of two or more aerials, at least one of which is movable, to simulate a much larger array. Data must be taken with the aerials in each of many different relative orientations, in order to obtain one "observation."

The 250-foot "dish" at Jodrell Bank is the largest fully steerable parabolic antenna. However, its surface is not suitable for use at centimeter wavelengths, and most of the important results in this frequency range have been obtained with smaller dishes, such as the 50-foot reflector at the Naval Research Laboratory and the nearly identical 85-foot reflectors at Michigan and Green Bank. Three large "filled aperture" telescopes have recently been put into operation; two, the 210-foot fully steerable dish at Parkes, N.S.W., and the 300-foot transit telescope at Green Bank, are paraboloids, and the other, a 1000-foot reflector constructed in a natural limestone sinkhole at Arecibo, Puerto Rico, has a spherical surface.

The 72-foot reflector at Serpukhov, U.S.S.R., dominates the field of millimeter wave radio astronomy. Smaller reflectors are in use at these frequencies in California and Texas, and another will be constructed on Kitt Peak, in southern Arizona.

Several approaches to the problem of the mechanical support of large, steerable reflectors have been tried. Among these are the Ohio State University instrument, which consists of a fixed parabolic section and a tiltable flat reflector, the parabolic strip antenna of Pulkovo Observatory, and the cylindrical paraboloid of the University of Illinois. Many other antenna configurations have been used or proposed by radio astronomers in response to the requirements of various observational programs.

Gain stability, phase stability and low receiver noise temperature are the prime desiderata in a radiometer. Compensation for gain variation by switching between the object signal and a reference standard was achieved by R. H. Dicke in 1946. Many refinements of this technique have since been developed. The problem of phase stability is greatest for long-base-line interferometers and multielement arrays; phase switching

and correlation techniques have generally been used in conjunction with these instruments. Traveling wave tubes, masers, parametric amplifiers and tunnel diodes have all been used to provide low noise amplification, particularly in the microwave region where the average intensity of cosmic sources is low. Multichannel receivers have received wide attention, especially for use in spectral line studies.

Cosmic Radio Sources. In the early stages of radio astronomy, any unidentified celestial radio source was generally called a *radio star*. However, as increased accuracy in the radio positions was attained, more and more radio sources were identified with optical objects, and it became clear that these sources were external galaxies, supernova remnants, etc., not stars. In fact, ordinary stars are very weak radio emitters, and therefore the only member of this class that has been studied by radio astronomers is the sun.

Solar radio waves are classified in terms of three basic components. The *quiet sun* radiation consists of the background thermal emission of the solar atmosphere. The *slowly-varying* component, characterized by a 27-day recurrence tendency, is produced in regions of enhanced density that form in the corona above solar active regions; V. V. Zheleznyakov, and also T. Kakinuma and G. Swarup have shown that it can be explained in terms of radiation by thermal electrons at the gyrofrequency and its harmonics (*resonance absorption*). Coronal temperatures inferred from the quiet sun and slowly-varying components are about 10^6 °K. The *solar bursts* constitute the third component. They may occur as isolated events with durations as short as 10^{-2} second, in groups, or in "storms" that may persist for several days. The bursts that occur in different regions of the radio spectrum differ in their observed properties, as well as in their places and modes of origin. The mechanisms by which the bursts are generated have not been satisfactorily discussed for all types of events; however, the explanation of certain kinds of bursts in terms of plasma oscillations, and others in terms of the synchrotron process, is generally accepted.

It has been known for some time that certain cool ($T \approx 2900$ °K, typically) dwarf stars show large, rapid, nonpredictable increases in optical brightness. Recently, A. C. B. Lovell, F. L. Whipple and L. H. Solomon have studied several of these *flare stars*. They found that radio bursts of much greater absolute intensity than the average solar event are associated with the optical flares of these stars. Analysis of the data revealed that the velocities of light and radio waves are the same to 4 parts in 10^7 ; thus a combination of optical and radio astronomy observations has provided physicists with what is at present the most accurate experimental proof for the non-wavelength-dependence of the velocity of electromagnetic radiation.

During the past decade, interest in planetary astronomy was revived, first by the results of radio observations and subsequently by the advent of the "Space Age." The first radio detection of

Mercury was made in 1961 by W. E. Howard, A. H. Barrett and F. T. Haddock, who used the 85-foot Michigan reflector. The preliminary analysis of observations made with the 210-foot Parkes telescope, recently reported by K. I. Kellermann, suggests that the temperature differential between the light and dark sides of Mercury is small compared to the average value of about 300°K. The simplest explanation for such a result, namely heat transport by atmospheric processes, is in direct contradiction to simple physical theory, which suggests that Mercury should be unable to retain an atmosphere. Extensive observations by many workers have shown that the microwave spectrum of Venus resembles that of a blackbody at the unexpectedly high temperature of 600 K. Observations of limb darkening, made with the Mariner II space vehicle at a wavelength of 1.9 cm, appear to have ruled out the possibility that the microwave emission arises in a dense ionosphere, and at present, a strong *greenhouse effect* seems to be the most reasonable explanation. American, British and Soviet radar astronomers have independently found that Venus rotates in the retrograde sense. As early as 1956, C. H. Mayer, T. P. McCullough and R. M. Sloanaker at the Naval Research Laboratory showed that the brightness temperature of Mars at wavelength 3.15 cm is about 200°K, in reasonable agreement with infrared measurements. In 1964, a temperature of 1100°K at 21 cm was found at Jodrell Bank, but this result has not been substantiated by subsequent work. In 1955, radio bursts from Jupiter were accidentally discovered by B. F. Burke and K. L. Franklin of the Carnegie Institution. Their report led C. A. Shain to identify over 50 previously unidentified Jovian bursts in pre-discovery Australian radio observations; he also inferred the existence of a localized burst source on the planet from the fact the frequency of burst occurrence depended on the longitude of the Jovian central meridian. At present, due chiefly to long series of observations made at Yale, Florida and Colorado, it is known that the Jovian bursts occur in the frequency range below 45 Mc/sec and that they originate in several distinct sources with angular diameters of 15 seconds of arc or less. The occurrence rate of the bursts appears to be correlated with the position of some Jovian satellites. Continuous radio emission, in both the spectral and temporal senses, is observed in the decimeter region. It has a nonthermal spectrum and originates in a region whose equatorial radius is about three planetary radii and whose polar radius is about one planetary radius. Recently, J. R. Dickel at Michigan has extended the observations of this component to a wavelength of 1.8 cm, where thermal emission may also be important. The theoretical explanation for the various components of the Jovian radiation is still a matter of considerable controversy. Several groups have detected Saturn in the wavelength range 3 to 21 cm, but this work is still in a preliminary state. Radio detection of the three outermost planets has not yet been accomplished.

In addition to the well-known radar echo experiments, radio observations of the moon in the wavelength range 4 mm to 75 cm have been carried out extensively since 1946. The radiation is thermal in origin and has generally been studied from three points of view: the comparison of radio emission from different features of the lunar topography, the dependence of the emission on the phase of the lunar cycle, and the study of variations in the emission that occur during eclipses of the moon. The amplitude and phase lag of the emission shows that it originates in a thin region just below the lunar surface, and attempts have been made to interpret the results in terms of layers of dust and rock.

At a 1944 Leiden Observatory colloquium, H. C. van de Hulst predicted that a spectral line could be observed by radio astronomers, who previously had worked only in the continuum. He referred to the 1420-Mc/sec hyperfine transition in the ground state of neutral hydrogen, the now-famous 21-cm line. Seven years later, H. I. Ewen and E. M. Purcell at Harvard made the first successful detection of this radiation. The importance of the 21-cm line is twofold: (1) it originates in the most abundant known constituent of interstellar matter; (2) Doppler shifts are readily measurable in line radiation but not in the continuum. As a result of many 21-cm investigations, notably those of the Harvard, Leiden and Australian groups, it has been possible to map the distribution of interstellar hydrogen in the galaxy and to study the dynamics of the gas. In 1963, A. H. Barrett, M. L. Meeks, and S. Weinreb at M.I.T. succeeded in detecting the 18-cm lines of OH. Already, further studies have shown that the properties of the interstellar gas as determined from the hydroxyl radical differ in several respects from those revealed by the hydrogen line. Hydrogen-line measurements have now also been reported for several dozen external galaxies. Interstellar clouds in the vicinity of hot stars may become photoionized (*H II regions*). Observations of the thermal radiation from such objects, generally made on decimeter and centimeter waves, lead to estimates of temperatures, electron densities, and total masses; further, the structural details revealed by high-resolution observations, such as those made by Y. Terzian at Green Bank, are of great interest to the theoretician. Radio detection of several *planetary nebulas* has also been achieved.

A number of radio sources have been identified with the remnants of galactic supernovae, some of which were unknown prior to the radio observations. Their brightness distributions tend to be circularly symmetric, sometimes with indications of shell structure, but condensations and filamentary detail are also found. The observations are in accord with the suggestion of I. S. Shklovsky that the radiation is produced by the synchrotron process. Measurements of Cassiopeia A, the remnant of a Type II supernova that exploded in about 1700 A.D., have confirmed Shklovsky's prediction that the radio flux should decrease by about 2 percent per year, independent of frequency.

To the radio astronomer, there are two categories of galaxy. A weak emitter, or *ordinary galaxy*, (such as our own system) typically radiates 10^{38} erg/sec in radio waves, compared with 10^{44} erg/sec in the optical region. The strong emitters, or *radio galaxies*, each produce up to 10^{45} erg/sec in the radio range alone. In both types of galaxy, the radio continuum is accounted for on the synchrotron theory. Radio data on ordinary galaxies have been rather sketchy, due to the small number of positive detections. Recently, however, D. S. Heeschen and C. M. Wade at Green Bank have made a systematic study of bright galaxies; they conclude that all normal spiral and irregular galaxies are probably weak radio sources. On the other hand, the strong emitters tend to be elliptical galaxies, often distinguished by peculiar optical phenomena, and they are believed to constitute the bulk of the nearly 1300 discrete sources (most are not yet identified) listed in the General Catalogue of W. E. Howard and S. P. Maran. The early results indicate that these sources have power-law spectra, but the more accurate data now available show the presence of curvature in many spectra (as displayed in a log frequency-log flux diagram, where a power law is a straight line), and W. A. Dent and F. T. Haddock at Michigan have demonstrated the value of observations below wavelength 4 cm in defining the spectral shape. The interferometric studies of A. T. Moffet and P. Maltby at California Institute of Technology and of J. Lequeux at Nançay, enabled them to divide the resolved sources into three groups, on the basis of brightness distribution: *simple*, *double* and *core-halo* sources. C. Hazard and M. B. Mackey at Sydney have used the method of lunar occultations to resolve detail as small as 0.5 second of arc and have detected triple and even more complex structure in some sources. Moffet has recently reexamined several double sources with improved resolution and has found that the emission in a given lobe tends to be concentrated at the end furthest from the other lobe, in accord with an expanding model. Linear polarization measurements at several frequencies have made it possible to study depolarization and the rotation of the electric vector as a function of frequency, leading to model-dependent estimates of the electron density and magnetic field strength in interstellar and intergalactic space as well as in the sources themselves. Similar estimates for the sources are obtained from the radio spectra and angular diameters, combined with distances obtained from application of the Hubble law to optically observed redshifts, according to the method of G. R. Burbidge (see COSMOLOGY).

The identification in 1963 of a new class of radio source the *quasi-stellar objects*, now called "quasars," had a profound impact on physics and astronomy. Originally thought to be peculiar stars within our galaxy, the quasars are now known to be among the most distant objects in the universe. Although their radio emission typically is similar to that of a strong radio

galaxy and the optical emission rates are up to 100 times greater than those of any known galaxy, they occupy volumes that are extremely small compared to typical galactic dimensions. Detailed optical studies of quasars are mostly limited to the very largest telescopes. A. R. Sandage at Mount Wilson and Palomar Observatories has recently discovered several dozen of these objects, but our knowledge of them is limited, and the theoretical explanations of the vast energies involved are still in the speculative stage.

Radio Astronomy and Cosmology. The several methods that are suitable, in principle, for testing between world models on the basis of radio observations include (1) the measurement of background extragalactic radiation, (2) the determination of the number of sources in each flux-density range, and (3) the analysis of the relation between the angular diameters and the flux densities of sources. However, these tasks are very difficult, and the only reasonably certain result thus far obtained is that of M. Ryle, who found that the number-flux density relation is not in accord with the basic version of the steady-state theory.

RADIOACTIVE TRACERS

The use of radioisotopes as tracers rests on the nearly indistinguishable physical and chemical properties of all the isotopes of a given element. Proper incorporation into a material of a radioisotope, that can be measured with appropriate radiation detectors, provides a means of studying the behavior of the material or a component thereof. Thus, a radioisotope may be used to study the chemistry or physics of an element, a chemical compound, or a mixture of substances. For example, I^{131} , a radioisotope with an eight-day half-life, has been used to study the distribution of iodine in multiple phase systems, to study the biochemistry of I^{131} -tagged diiodotyrosine, and to measure the flow rates of underground streams.

Shortly after the end of World War II, the U.S. Atomic Energy Commission made a variety of radioisotopes available from the Oak Ridge National Laboratory. Subsequently, additional suppliers have been established in the United States and in other countries. One may now purchase useful radioisotopes of 68 out of the 81 "stable" elements. Isotopes of very short half-life

(minutes to an hour or so) exist for another 10 "stable" elements. Useful radiotracers are completely absent only for the elements, He, Li, and B. Most radioisotopes are produced in nuclear reactors by fission or other neutron-induced reactions; however, some are produced with accelerators. Available radioisotopes, their sources and their prices are catalogued in "The Isotope Index, 1963-1964," J. L. Sommerville, Editor, Scientific Equipment Co., Indianapolis, Indiana, 1963.

Facilities for the formation of radioactive tracers directly within a sample or test material have also become available. For example, it is possible to form radioactive iron 59 within a sample of steel by irradiating the sample in a nuclear reactor.

The wide choice of radioisotopic tracers and the availability of sensitive detection systems to fit most circumstances have made possible the use of radiotracer techniques in many branches of science, medicine, and industry. Radiotracers have a number of features that make their use generally attractive. Unlike other types of tracers, they provide unequivocal evidence of their presence by virtue of their own radiation. Most species of radioisotopes are inexpensive (although incorporation into a specific compound can be somewhat costly), and detection equipment can be obtained at moderate expense. Also, due to the excellent detection efficiency of available equipment, it is possible to carry out most experiments without undue health hazards. Investigators trained in the safe handling of radioisotopes can follow gas, liquid, solid, or mixed-state systems at the laboratory, pilot-plant or even full plant scale with complete safety.

The following examples of radiotracer applications comprise but a partial list of uses.

Absorption of gaseous or liquid-phase constituents can be readily studied with the aid of radiotracers. Either the deposition of tracer onto the substrate or the disappearance of tracer from its initial phase may be measured.

Analysis of chemical composition may be accomplished either by utilizing the reaction of tagged reagents or by "isotope dilution." An example of the former method is the use of Ag^{110} -tagged silver nitrate reagent in chloride determinations by the precipitation of $AgCl$ from solution; a sharp rise in liquid-phase radioactivity indicates the point of essentially complete chloride precipitation. Isotope dilution utilizes an isotope of an element to measure the amount of the same element in a sample. It is based on the fact that the amount of radioactivity per unit weight of the element or compound (specific activity) in the tracer reagent will be decreased when the reagent is added to a solution containing the naturally-occurring element or compound. The change in specific activity is an analytical measure of the amount of the element or compound originally present in the sample.

Radiotracers may be used as analytical adjuncts, also. They provide a convenient means of checking the degree of completion of analytical steps, such

as precipitation and extraction, and can provide a measure of chemical losses in analytical procedures. They may be used to mark compound locations in chromatographic separation procedures.

Many other aspects of chemistry have been elucidated with radiotracer techniques. Chemical reaction rates, equilibria, and mechanisms have been studied. Diffusion rates, exchange rates, solubility products, partition coefficients, dissociation constants, and vapor pressures have been measured. Processes due to the effects of high-energy radiation, photolysis, and catalysis have been unraveled. Many of the recent advances in biochemistry would not have been possible without the use of radioactive tracers, especially in the study of biological catalysis (enzyme reactions).

Many of the above subjects have been studied in connection with fields other than chemistry. Thus, while diffusion rates are of interest in elucidating rate-limiting chemical processes, they are also of considerable interest in electronics, metallurgy, and process industries. The self-diffusion of alloy components as a function of alloy composition and grain substructure has been investigated. Diffusion in other solid-state materials, such as semiconductors, has been measured. The specific sulfide surface area of metal sulfides supported on alumina has been determined by exchange of normal surface sulfur with S^{35} -tagged H_2S . The rate of such exchange is of interest, and the final equilibrium state gives a measure of the surface sulfide area. These are examples of problems that are not amenable to solution with techniques other than the radiotracer method.

Industry has obtained marked economic benefits from radiotracer applications. Corrosion and wear studies can be carried out with rapidity and insight otherwise impossible. The corrosion of a steel pipe containing Fe^{59} (produced by irradiating a section of pipe) can be followed *in situ* by measuring the appearance of radioactivity in the corrosive medium or by following the disappearance of radioactivity of the part. Similarly wear of an irradiated part such as a piston ring, cylinder sleeve, or gear, can be measured *in situ*. Prior to the availability of radiotracers, such wear studies required frequent dismantling of machinery for weight measurements. Furthermore, it is now often possible to obtain detailed wear or corrosion patterns by autoradiography. The techniques used in wear studies have also been used to study the effectiveness of lubricants and the mechanism of wear prevention.

Radioactive tracers have been used to examine fluid processes. They are highly useful in detecting leaks and are used routinely to mark the interface between two different products moving consecutively through a pipe-line. The gamma rays from an isotope such as Ba^{140} in soluble form at the interface can be discerned easily through the walls of the pipe. In a similar fashion, flow rates may be measured by quickly injecting a tracer

into a stream and noting the time required for the radioactive pulse to travel the distance between two detectors or between the injection point and a single detector. Rapid injection and accurate timing may be avoided where the amount of radioactivity injected and the detection efficiency of a downstream detector are accurately calibrated. The total signal from the tracer is inversely proportional to the velocity with which it goes past the detector. The techniques have been used in pilot plants, refineries, chemical plants, and even to study the flow rates and patterns of rivers and ocean currents.

The disposition of materials in various process units has been evaluated. Stream splitting, recycling, residence times, entrainment in distillations, mixing, and unit inventories have been measured.

The techniques of use in industrial fluid processes also apply in other fields. Stream splitting in capillary gas chromatography sampling units has been studied. Blood flow rate, total blood volume, and heart function are examples of medical applications.

RADIOACTIVITY

Radioactivity is the term applied to the spontaneous disintegration of atomic nuclei. It was one of the first and most important phenomena which led to our present understanding of nuclear structure. Credit for the discovery of radioactivity is usually given to Henri Becquerel, who made the observation in 1896 that penetrating radiation was given off by certain compounds of heavy elements in the absence of any external stimulus. Many other scientists were working in the field of radiation, however, and the announcement by Becquerel led to a flood of discoveries about the nature of the radiations which were emitted. A

* Both books contain abundant references to other works, general and specialized, concerning radioactive tracers.

number of workers determined that certain of the radiations from these radioactive substances could be deflected in a magnetic field, and by 1900 three separate types of rays were identified. They were given the names alpha, beta, and gamma rays.

Distinction is frequently made between natural radioactivity, which was observed by the early workers, and artificial radioactivity which was first produced by Joliot-Curie and Joliot in 1934. These workers bombarded Al^{27} with alpha particles to produce P^{30} . For purposes of our discussion, we shall not distinguish between the sources of the radioactive material.

A discussion of radioactivity requires that mention be made of the stability of nuclei. Stable nuclear species or nuclides exist for all elements having proton numbers in the range from 1 to 83 except for elements 43 and 61 (technetium and promethium). In general, elements having even atomic numbers have two or more stable isotopes, whereas odd-numbered nuclei never have more than two.

The assumption is usually made that all possible nuclides were formed in the original atomic production processes, and that those which remain at the present time do so because of some inherent stability. In general, this stability involves the neutron-proton ratio, and a number of theoretical studies have been undertaken to determine the conditions for the maximum stability for nuclei.

Stability may be considered from three different standpoints: relative to the size and the number of particles in the nucleus, the ratio of the neutrons and protons in the nucleus, and the ratio of the total mass-energy of the nucleus. A nucleus which is unstable with respect to its size will emit alpha particles whereas a nucleus unstable with respect to its neutron-proton ratio may emit a negative or positive electron or may capture an electron. If a nucleus is unstable with respect to its total energy, the excess energy may be given off as gamma radiation which is electromagnetic in nature. Let us consider these emissions in more detail.

Alpha Emission. It is evident that there are two types of forces existing in the nucleus. The first is a disruptive force arising from the repulsion of similarly charged particles. In addition, however, there are very strong attractive forces arising from the interactions of the nucleons. These attractive forces are very strong within the nucleus, but drop off quite sharply beyond about 10^{-12} cm from the center of the nucleus. Alpha particles, consisting of two protons and two neutrons, are, with certain exceptions, observed to come only from the larger nuclei. The mechanism of the emission process, however, is not a simple force phenomenon.

If we make calculations involving only the energies of the nucleus and the ejected particle, we would find, for example, that an alpha particle should come from a Ra^{226} nucleus with approximately 27 Mev of energy. Instead, the emerging particle is observed to have about 5.3 Mev. This difference in energy cannot be explained using

classical energy computations. The explanation of the alpha emission is usually given in terms of a "tunneling" effect, which is a quantum mechanical description first developed by Gamow and by Gurney and Condon. There are two equivalent ways of looking at this effect. One is to consider the alpha particle as being in motion inside the nucleus. In this picture, we visualize the particles as striking the potential "wall" of the nucleus. According to the quantum mechanical treatment for a particle striking such a barrier, there is a finite probability of passing through the barrier and appearing on the outside. Calculations making use of this probability give correct values for the observed half life and energies of the alpha particles from radioactive nuclides.

The other description of this process considers the alpha particle as being a wave packet with a very high probability of being found within the nuclear radius, but also having a finite probability of being outside the nucleus. According to this notion, the probability of finding the alpha wave packet at a distance greater than the nuclear radius, likewise gives the proper lifetime and energy values. It can be shown that this type of radioactivity is more probable in elements of high atomic number, and present extrapolations for this type of instability suggests that the highest atomic number element which can exist may be in the region of 108 or 109. It appears that elements 105 and higher will not exist long enough to be identified chemically, since the alpha emission will be extremely probable, affording an extremely short half-life.

Beta Radiation. There are over 400 nuclear species which have been artificially produced in the laboratory. Nearly all of these have been produced by the reactions which give rise to a net gain or loss of neutrons from the stable nuclei. In such a case the residual nucleus is characterized by having a neutron-proton ratio higher or lower than stable nuclei of that element. Similarly, if one considers alpha-emitting nuclei as being the "stable" nuclides for elements above lead, certain nuclides may be formed after the alpha emission with neutron-proton ratios higher or lower than the original element. The general decay process for nuclides with differing n/p ratios involves the reorganization of the nucleus in a manner which will leave a nucleus having a neutron-proton ratio corresponding to that requisite for stability.

Let us first consider the case in which a nucleus has a neutron-proton ratio higher than a stable isotope of that element. For example, the nuclei of all stable phosphorous atoms contain 15 protons and 16 neutrons. If a nuclear reaction takes place which leaves a nucleus with 15 protons and 17 neutrons we have a nucleus of P^{32} . Since only P^{31} occurs in nature, we know that some adjustment will take place to bring about stability. In this case, one of the neutrons is transformed into a proton, a negative electron, and a neutrino (specifically an anti-neutrino) which is shown in the following reaction:

The negative electron cannot exist as part of the nucleus and is ejected from the nucleus along with the neutrino. When the electron is investigated, it is found to be identical to other negative electrons, but when it is formed in this process, it is given the name negatron or negative beta particle. The residual nucleus then contains 16 protons and 16 neutrons. The element possessing 16 protons is sulfur, so the nucleus resulting from this negative beta emission is S^{32} . In general, then, nuclei with neutron-proton ratios higher than stable nuclei eject a negative electron from the nucleus and are thus transmuted into a nucleus of the next higher atomic number.

There are also types of nuclear reactions which may leave a nucleus with a neutron-proton ratio lower than the corresponding stable nucleus. In this type of instability, there are two processes which may compete with one another for the production of a stable nucleus. In the first of these, an extranuclear electron may be captured by the nucleus and combined with one of the protons. The most likely electron taking part in this process is one from the K level. L or M level electrons may be "captured," however. This electron capture reaction may be shown as follows:

A neutrino is also ejected in this process. When this reaction takes place, the nucleus then contains one less proton than before, and is thus a nucleus of one lower atomic number. For example, if Fe^{55} "decays" by electron capture, the resulting nucleus of Mn^{55} is stable. This process can take place whenever the neutron-proton ratio is too low for stability.

The reaction which competes with electron capture may occur if the neutron-proton ratio is low, and if there exists a certain minimum mass-energy difference between the unstable nucleus and a possible stable nucleus having one less proton. If there is at least 1.02 Mev mass-energy difference a proton may transform into a neutron, a positive electron (or positron), and a neutrino according to the following equation:

The positron is then ejected from the nucleus. The characteristics of the positron are identical to those of the negatron except for its positive charge. A number of cases are known in which both electron capture and positron emission processes take place in the same nuclear species. A radioactive nuclide is characterized as having a certain "branching ratio" when more than one type of decay is possible.

Gamma Radiation. The usual modes of decay which involve the re-organization of the nucleus are those described above. In many cases, however, another step is involved in attaining final stability. After one of the nuclear transformations described above takes place, the nucleus may still possess excess energy. In this case, the extra energy is given off directly as gamma radiation. These are electromagnetic radiations which have energies corresponding to the difference in energy

levels in the nucleus from which they come. A particular nuclide thus exhibits a certain pattern or disintegration scheme by which it decays. For example, P^{32} decays by negative beta emissions, which are not followed by gammas. On the other hand, Co^{60} emits negative beta radiation which is followed in each case by two gamma rays in cascade. These gamma radiations have energy of 1.17 and 1.33 Mev respectively. In general, the gamma radiations are emitted in time periods less than 10^{-12} seconds following the first transmutation step. In some cases, however, excited energy states may exist for significantly longer periods. Experimental determinations of the lifetimes of these slower gamma ray transitions range from 10^{-8} second to several months. If such an excited state exists in a nuclide for a period long enough to be measured experimentally, the nuclide is called a nuclear isomer, and the transition process involving such gamma radiation is called an isomeric transition (I.T.).

It should be mentioned also that gamma radiation is given off following nuclear reactions. Such gamma rays called "capture" or "prompt" are discussed in conjunction with nuclear reactions, although isomeric states are often formed in this manner, and isomeric transitions may leave the nuclei in radioactive rather than stable states.

Decay Schemes and Units. Information as to the radioactive transitions which take place in a given case are frequently presented in what is called a decay scheme. A group of simple decay schemes is shown in Figure 1. These indicate the type of radioactive process which the nucleus undergoes, the energies of the radiations given off, and the branching which may take place. Most nuclei have decay schemes which are much more complex than those represented in the Figure, but they involve only multiple occurrence of the processes which have been described.

Decay Rate. It can be seen from the foregoing that a nucleus may change from an unstable to a stable form by one of several decay processes. We can thus speak of the decay rate of a sample of radioactive material in disintegrations per unit time—usually disintegrations per second. This refers specifically to the transformation of the nucleus, and does not give any indication of the kind or energy of the radiations emitted. The unit of activity is the "curie" and is defined to be 3.7000×10^{10} disintegrations per second. Submultiples or multiples of this unit in common use are micro-, milli-, kilo-, and megacurie. A sample containing one millicurie of radioactive material is a sample which decays at the rate of 3.7000×10^7 disintegrations per second.

We have no way to determine when any given nucleus will decay, but some of the most important work in the early study of radioactivity involved the study of decay rates. It was shown very early that the rate of radioactive decay is proportional to the amount of the radioactive material present. This can be expressed in the following equation:

$$A = -\lambda N$$

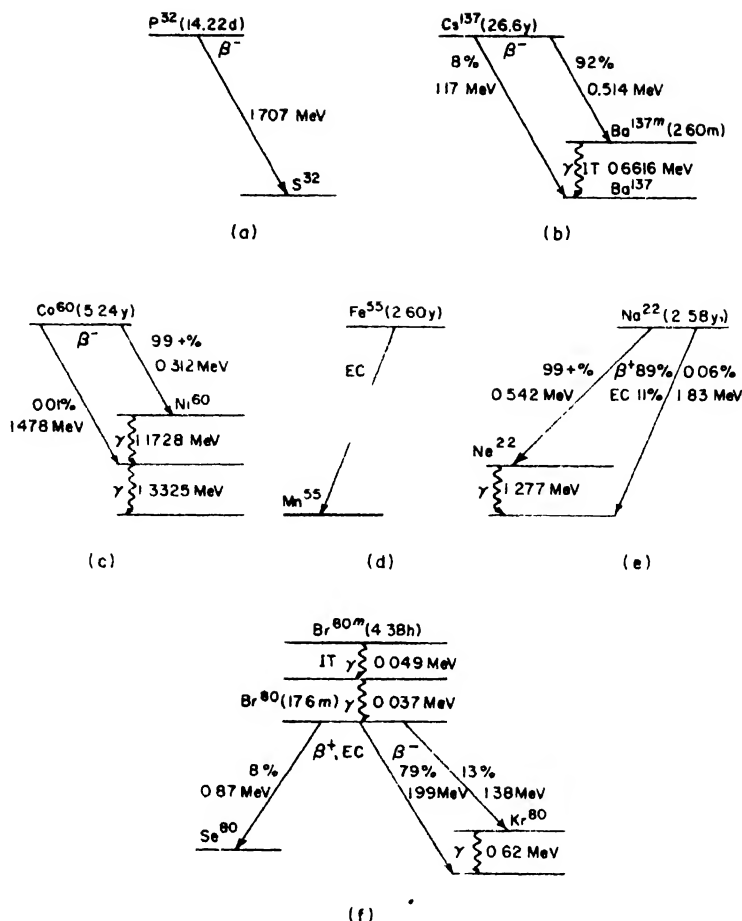

FIG. 1. Decay schemes.

in which A is the disintegration rate, N is the number of radioactive atoms present, and λ is a proportionality constant characteristic of each radioactive species. This relationship is sometimes important, but often a more useful relationship is the following:

$$N = N_0 e^{-\lambda t}$$

in which N_0 is the number of atoms present at some reference time, and N is the number of atoms present at some time t later, and e is the base of the natural logarithms. This exponential decay relationship is of fundamental concern in working with radioactive materials, even though it is valid only for a statistically large number of atoms (i.e., all unstable nuclei will eventually decay).

The above equations are valid for any single radioactive species, and the exponential expression states that a given fraction of nuclei will decay in a given time period. In practice, we frequently refer to the time required for one-half of the atoms to decay. This is called the half-life of the radioactive material. It is related to the

decay constant in the following way:

$$T_{1/2} = \frac{0.693}{\lambda}$$

It can also be shown that the average life, $\tau = 1.44$ times the half-life.

There are many cases in which a series of radioactive steps take place. For example, U^{238} undergoes 14 successive decays before arriving at the stable end product, Pb^{206} . These steps involve the emission of successive alpha and beta rays along with gamma radiation in some cases. Although the calculations are somewhat more complex, it is possible to determine the disintegration rate of each of the daughter radioactive species formed in these processes. Details of this type of calculations are given in the references below.

RAMAN EFFECT AND RAMAN SPECTROSCOPY

The Raman effect is the phenomenon of light scattering from a material medium, whereby the light undergoes a wavelength change in the scattering process. For a given medium, the Raman scattering per unit volume is of the order of one-thousandth of the intensity of the ordinary or Rayleigh scattering, in which there is no change of wavelength (see LIGHT SCATTERING). The Raman-scattered light bears no phase relationship with the incident light, whereas the Rayleigh light is a residual effect resulting from the departure of the incident and the scattered light from complete mutual coherence. The Raman intensity per molecule is thus independent of the state of the medium, apart from a certain small refractive index effect. The Rayleigh intensity per molecule, on the other hand, depends strongly on the degree of randomness of the spatial positions and orientations of the molecules of the medium; it is small for a crystal at the absolute zero and greatest for a gas at low density.

Scattering of light with change of wavelength was predicted in 1923 by Smekal, inspired by the discovery of the Compton effect. The Raman effect was discovered experimentally in 1928 in India by Raman and Krishnan, who showed that the spectrum of the scattered light of liquids and solids, strongly illuminated with monochromatic light, contains frequencies which are not present in the exciting light and which are characteristic of the scattering medium. Independently, and almost simultaneously, Landsberg and Mandelstam in Russia discovered the effect in crystals. The phenomenon is called combination scattering of light in present-day Russian literature.

The method of observing the Raman spectrum is usually some modification of the arrangement introduced originally by R. W. Wood. The specimen, e.g., a liquid contained in a tube 1 cm in diameter and 10 cm long, is strongly illuminated along its length by mercury arcs, with filters interposed between the arcs and the tube to isolate monochromatic radiation if necessary. The scattered light is observed along the axis of the tube through a plane window at one end of the tube. The other end of the tube is usually drawn out in a cone which, when blackened, forms a dark background against which the

scattered light is observed. The scattered light is analyzed by a spectrograph or recording spectrometer.¹

The experimentally confirmed laws of Raman scattering are as follows:

(a) The pattern of Raman lines, expressed as frequency shifts from the exciting line, $\Delta\nu_i$ ($i = 1, 2, \dots$), is independent of the exciting frequency.

(b) The pattern of Raman frequency shifts, $\Delta\nu_i$, is symmetrical about the exciting line. However, the lines on the low-frequency side of the exciting line (Stokes lines) are always more intense than the corresponding lines on the high-frequency side (anti-Stokes lines). The ratio of the intensities of corresponding anti-Stokes and Stokes lines is $I_a/I_s = \exp(-\Delta\nu_i hc/kT)$, where the Raman shift $\Delta\nu_i$ is expressed as usual in cm^{-1} . Thus anti-Stokes lines for $\Delta\nu_i > \sim 1000 \text{ cm}^{-1}$ are too weak to be observed at room temperature.

(c) A given Raman line shows a degree of polarization which depends on the origin of the line and on the experimental arrangement. For strictly transverse observation, i.e., observation at right angles to the incident light, the depolarization factor, ρ_n , has a value in the range 0 to 6/7 for unpolarized incident light.

Fig. 1 shows a schematic diagram of the Raman spectrum of carbon tetrachloride. The four Raman shifts, $\Delta\nu_i$ ($i = 1, 2, 3, 4$), are 218, 314, 459 and 775 cm^{-1} ; the corresponding values of ρ_n are 6/7, 6/7, 0, and 6/7.

The Raman shifts, $\Delta\nu_i$, correspond to energy differences (in cm^{-1}) between discrete stationary states of the scattering system. Thus, in the quantum picture, the incident photons collide *elastically* with the molecules to give Rayleigh scattering, or *inelastically* to give Raman scattering, the latter process being much less probable than the former. For a Stokes Raman line, the photon furnishes energy to raise the molecule from a lower to a higher state; for an anti-Stokes line, the molecule must furnish energy to the scattered photon and move to a lower energy state. The anti-Stokes line thus originates in a less highly populated state and is weaker than the corresponding Stokes line. The Raman process can be described classically, but not as accurately, as the modulation of the scattered light wave by the internal motions of the scattering molecule, the Raman lines constituting "sidebands" of the Rayleigh "carrier" frequency.

A rigorous theory of the Raman effect, based on the quantum theory of dispersion, has been given by Placzek.² The process of light scattering can be visualized as the absorption of an incident photon of frequency, ν_0 , by a molecule in a given initial state, thus raising the molecule to a "virtual" state from which it immediately returns to a final state emitting the scattering photon.

Fig. 2 illustrates the production of the Rayleigh line and Stokes and anti-Stokes Raman lines for a two-level system. If the frequency of the exciting light is such that the virtual state coincides with a real energy state of the system, the Raman effect goes over into molecular fluorescence provided

FIG. 1. Schematic diagram of the Raman spectrum of carbon tetrachloride. The heights of the Raman lines represent their relative intensities.

the states involved can combine with one another according to the selection rules.

In principle, the Raman shifts, $\Delta\nu_i$, can represent energy differences between electronic, vibrational or rotational energy states. In practice, Raman spectroscopy has been concerned chiefly with the determination of vibrational frequencies of polyatomic molecules from the scattered light spectrum and the correlation of the observed frequencies with possible modes of vibration of the molecules. In this role, Raman spectroscopy forms an important complement to near-infrared spectroscopy which also furnishes precise information on molecular vibration frequencies.³

FIG. 2. Illustrating the production of Stokes (S) and anti-Stokes (A-S) Raman lines and the Rayleigh line (R) by an exciting frequency, ν_e , for a two-level system. The dashed lines represent virtual states of the system.

The so-called polarizability theory of Placzek² is an approximate theory which is particularly useful in relating observed vibrational Raman lines to the normal vibrations of the scattering molecule. In the equation, $m = \alpha E$, m is the electric dipole induced in the molecule by the oscillating light field E . The constant of proportionality, α , is the molecular polarizability, which can be developed in a Taylor series in the vibrational coordinate q ,

$$\alpha = \alpha_0 + (\partial\alpha/\partial q)_0 q + (1/2)(\partial^2\alpha/\partial q^2)_0 q^2 + \dots$$

The intensity of the fundamental Raman band, corresponding to the $v = 0$ to $v = 1$ transition where v is the quantum number of the vibration, depends essentially on the rate of change of polarizability, $\alpha' \equiv (\partial\alpha/\partial q)_0$, with respect to the coordinate q . The vibration is active in Raman scattering if, because of the symmetry properties of the vibration, α' is not identically zero. Also the depolarization, ρ_n , of a Raman band can be related by the polarizability theory to the symmetry of the vibration. Thus, the single polarized ($\rho_n = 0$) line of carbon tetrachloride at 459 cm^{-1} (Fig. 1) can be identified immediately with the "breathing" vibration of the CCl_4 molecule, and the three depolarized ($\rho_n = 6/7$) lines with the three degenerate vibration forms of the molecule.

Since the infrared activity of a molecule depends on the molecular dipole, whereas the Raman activity depends on the molecular polarizability, the selection rules for two types of spectra can be very different. An extreme case occurs for molecules with a center of symmetry: vibrations which are active in infrared absorption are not active in Raman effect and vice versa.

Although most investigations of the Raman effect have dealt with liquids and solids, i.e., high-density materials, systematic Raman studies of low-pressure gases have recently been made possible by the development of special equipment.^{4,5} Since the molecules in gases are freely

rotating, pure rotational Raman spectra and the rotational structure of vibrational bands can be observed. Here again, Raman studies supplement infrared investigations since the rotational selection rules are $\Delta J = 0, \pm 1, \pm 2$ for the former and $\Delta J = 0, \pm 1$ for the latter, where ΔJ is the allowed change in the rotational quantum number J .

The recent development of optical masers or lasers has great importance for the future of Raman research. It is probable that lasers will replace mercury arcs for excitation of Raman spectra. In addition, two new phenomena have been discovered which will undoubtedly enlarge the scope of Raman investigations. The first of these is the "stimulated" Raman effect,⁶ a coherent and directionally dependent form of Raman scattering, which results from the intense coherent electric fields set up in a medium through which laser radiation is passing. The second is the "inverse" Raman effect,⁷ in which, under certain conditions, the Raman lines appear as absorption lines on a continuous background.

RARE EARTHS

The rare-earth elements (also called "rare earths", "lanthanides" and "lanthanons") are a group of fifteen elements of similar properties in Group III of the periodic table. Their properties are somewhat similar to those of scandium, yttrium, and actinium in the same group. The rare earths have atomic numbers 57 to 71, inclusive, and are, in serial order: lanthanum (La), cerium (Ce), praseodymium (Pr), neodymium (Nd), promethium (Pm), samarium (Sm), europium (Eu), gadolinium (Gd), terbium (Tb), dysprosium (Dy), holmium (Ho), erbium (Er), thulium (Tm), ytterbium (Yb), and lutetium (Lu). The rare earths from lanthanum to samarium are called the "cerium earths"; those from europium to dysprosium are "terbium earths." Those from holmium to lutetium are called "yttrium earths" because of their resemblance to yttrium which is similar to and always occurs with the rare earths.

The rare earths are inner transition elements characterized by progressive filling up of the $4f$ electrons without changing the outer $5s^2 5p^6 5d^0$ or $6s^2$ levels, resulting in a concurrent decrease in atomic size. This reduction in atomic radii with increasing atomic number is known as the *lanthanide contraction*. In this respect, and also in chemical behavior, the rare earths resemble the actinides, the second rare-earth-like series beginning with actinium, which shows a similar *actinide contraction* (see TRANSURANIUM ELEMENTS).

Occurrence. The only commercial minerals of importance are monazite and monazite sand, and bastnasite. Monazite is a rare-earth-thorium phosphate which occurs as small crystals in many acid granites and is recovered from placers resulting from the weathering of such rocks. It also occurs in some pegmatites, but commercial pegmatite deposits are rare.

Bastnasite is a rare-earth fluorocarbonate which occurs in hydrothermal deposits associated with barite, fluorite, and calcite.

Important monazite deposits are placers in Idaho, beach sands in Florida, Brazil, and India, and massive pegmatite monazite in the Union of South Africa. Bastnasite deposits are found in California and New Mexico, but only the California deposit is important.

Other minerals, sometimes useful for the extraction of the heavier rare earths, are gadolinite, $\text{Fe}(\text{RE})_2\text{Be}_2(\text{Si}_2\text{O}_{10})$; samarskite, a rare-earth-iron-calcium-magnesium niobotantalate; and xenotime, an yttrium-earth-rare-earth phosphate.

The cerium earths predominate in monazite and bastnasite. Cerium is the most abundant rare earth, being comparable to boron in occurrence in the earth's crust. Promethium is found only in the products from uranium fission.

Properties. The elements are trivalent in most compounds. Cerium, praseodymium, and terbium exist in the tetravalent state, and samarium, europium, and ytterbium form easily oxidized divalent compounds. Due to similarities in atomic structure, many chemical properties of the rare earths are quite similar and vary only slightly from one rare earth to the adjacent neighbor. Consequently, their separation is difficult unless use is made of oxidation states other than the trivalent. With increasing atomic number, the rare earths become less basic, the salts generally become more soluble, and the differences between adjacent members decrease.

Ordinary rare-earth similarities are usually based on conventional chemical observations. Thus, in aqueous systems, the relatively large degree of hydration of rare-earth ions tends to mask differences. In non-solvent systems where the masking effect is not present, differences between rare earths are more apparent. Rare-earth metals and simple compounds do indeed show more marked differences, and the more sophisticated research on rare earths since about 1950 shows that mutual similarity is not necessarily an inherent property of these elements.

With the exception of lanthanum and lutetium, rare earth compounds show characteristic sharp

absorption bands in the ultraviolet and visible spectra. This absorption is responsible for the pastel colors of the colored rare earth salts (green Pr, pink Nd, yellow Sm and Ho, rose Er, and pale green Tm).

Transitions in the 4f electrons account for most unusual properties: sharp absorption spectra in the ultraviolet, visible, and infrared—useful in optical devices, in the study of spectra theories, and in lasers. Complete pairing or formation of complete inner electron shells, resulting in balancing of magnetic moments causes ions to be diamagnetic (as for La, Lu, and Y); unpaired electrons lead to paramagnetic ions (as for Dy, Tb, and Ho).

Rare-earth Metals. The metals have a silver-gray luster which tarnishes quickly in air if the metals are easily oxidized (La, Ce, Sm, Eu). Hardness varies from that comparable to lead (Eu, Yb), to tin (Ce, La), to zinc (Nd, Pr), to mild steel (Gd, Y). Densities (grams per cubic centimeter) vary from 6.18 for La and 6.8 for Ce to 9.8 for Tm and 7.0 for Yb. Melting points vary from 804°C for Ce to about 1700°C for Lu, and the boiling points are in the range 1490 to 4200°C.

Being active reducing agents, the metals react slowly with water and are soluble in dilute acids. They are pyrophoric when finely divided, cerium igniting in air at 150 to 180°C. Above 200°C, they combine directly with halogens, and they form nitrides with nitrogen above 1000°C. Interstitial hydrides approximating RH_2 or RH_3 are formed by absorption of hydrogen.

The mixture of rare-earth metals made commercially without appreciable separation of rare earths is known as "misch" metal. It contains about 22 per cent La, 50 per cent Ce, 18 per cent Nd, 5 per cent Pr, 1 per cent Sm, and 2 per cent other rare-earth metals. It is often sold as "cerium" metal.

Rare-earth Compounds. Common water-soluble salts are the acetates, chlorides, nitrates, and sulfates. The carbonates, oxalates, hydroxides, oxides, phosphates, and fluorides are insoluble. Cerous (Ce^{+3}) salts are similar to the other trivalent rare earth salts, while ceric (Ce^{+4}) salts are more like those of thorium. Trivalent acetates and sulfates show decreased solubility in hot solutions.

Acetates are made by treating the hydroxide, carbonate or oxide with acetic acid. Carbonates are precipitated by the addition of alkali carbonates to neutral rare-earth solutions; they are only slightly soluble in excess of alkali carbonate. Fluorides are precipitated in hydrated form on adding hydrofluoric acid or soluble fluorides to rare-earth solutions. The precipitates are insoluble in excess hydrofluoric acid and in mineral acids. Anhydrous fluorides are made by hydrofluorinating the oxides at elevated temperatures.

Chlorides, bromides and iodides are prepared by dissolution of the hydroxide, oxide, or carbonate in the halogen acid. The salts crystallize from water as hydrates. Anhydrous chlorides and bromides are made by heating oxides with the

ammonium halide, followed by sublimation of the excess ammonium salts in vacuum. Nitrates are formed similarly to the other water-soluble salts. They form many double nitrates with alkali and alkaline earth nitrates. Oxalates are precipitated from slightly acid solution with oxalic acid or alkali oxalates. They are important in the analysis for rare earths, and in the separation of rare earths from other metals. Hydroxides are precipitated from solution by alkali and ammonium hydroxides. The sulfates are characterized by their formation of sparingly soluble double sulfates with alkali sulfates. The most important double sulfate is the sodium salt, $RE_2(SO_4)_3 \cdot Na_2SO_4 \cdot 2H_2O$.

Extraction and Separation. The extraction of rare earths from monazite is commercially important. The ore is opened by heating with sulfuric acid to form anhydrous rare-earth and thorium sulfates and phosphoric acid, or by heating with sodium hydroxide solutions to form rare-earth and thorium hydroxides and sodium phosphate. The reaction products are lixiviated in water, and if the alkaline method is used, the washed rare-earth-thorium hydroxides are dissolved with acid.

Thorium is separated from the rare earths by fractional basicity precipitation or by precipitation of compounds such as thorium pyrophosphate. Rare earths are usually recovered from the thorium filtrates by precipitation of the double rare-earth sodium sulfate. The double sulfate precipitate is converted to rare-earth hydroxide which serves as the starting material for making commercial rare-earth salts.

Cerium is separated from the rare earths by oxidation to the tetravalent ceric state, followed by basicity separations or crystallizations of insoluble ceric compounds. Ceric salts are generally much less soluble than those of the trivalent rare earths. Crystallization of ammonium hexanitratocerate or ammonium trisulfatocerate, precipitation of basic ceric nitrates or sulfates, and fractional basicity separations with the hydrous oxides are commonly used procedures to separate and purify cerium.

Separation of the cerium-free rare earth mixture (often called "didymium") formerly was done by long series of fractional crystallizations and fractional precipitations. Ion exchange and solvent extraction methods of separation have replaced tedious fractional crystallization, and are used commercially to produce both technical and ultrahigh-purity rare earths. Exclusive of non-rare earth impurities, the purity of commercially available individual rare-earth compounds is usually 99.9 per cent, and in some cases as high as 99.9999 per cent.

Uses. Most uses are based on unseparated rare-earth mixtures, or on technical cerium and "didymium" materials. About one-fourth of the rare-earth salts produced are used in carbon arc lighting. Rare-earth-cored carbons are indispensable to the motion picture industry and are also used in military searchlights.

Rare-earth metal (misch metal) and cerium

metal are important in the manufacture of lighter flints and certain alloys. Rare-earth-zirconium-magnesium alloys have outstanding high-temperature properties. Certain types of ferrous and stainless alloys are improved by the addition of misch metal or rare-earth compounds.

Rare-earth salts have important uses in the coloring and decolorizing of glass. Specially prepared cerium oxide and rare-earth oxide are widely used in polishing spectacle and optical instrument lenses, as well as mirrors, glass products, and granite.

Miscellaneous uses of the rare earths are: lanthanum oxide in silica-free optical glass, neodymium oxide as a coloring material for novelty glassware, "didymium" salts in temperature-compensating ceramic capacitors, rare-earth oxalate as a nausea preventive, rare-earth compounds as activators in phosphors, and various rare-earth salts in catalyst manufacture. Cerium compounds are used as laboratory reagents and as scavengers in explosive manufacturing.

As nuclear poisons, Sm, Gd, Eu, and Dy materials are useful because of the very high neutron cross sections of some of their isotopes.

Yttrium oxide is a component of microwave ferrites of the garnet type. Most of the individual rare earths are important as host materials or dopants in laser crystals.

REACTOR. *See* NUCLEAR REACTORS.

REACTOR SHIELDING

Currently, nuclear reactors utilize the FISSION process to "burn" uranium or plutonium fuels. In this process, radiations are emitted which must be intercepted to prevent them from injuring nearby personnel or equipment. The material which does so is called shielding. In the FUSION process, which may some day be used in another type of nuclear reactor, energy is released by charged-particle reactions, principally those involving deuterium or tritium. The radiations from these reactions are not as intense as those from the fission process. In order to solve a shielding problem, it is required to know the sources of radiation, the mechanisms for interaction of this radiation with matter, the tolerable levels of radiation, and the most efficient and precise methods of calculating the attenuation of that

radiation on its passage through a radiation shield.

Sources of Radiation. Prompt Neutrons. In a fission event, the fission fragments are produced in a highly excited state so that they boil off neutrons as they travel away from the site of the fission. These neutrons, called prompt neutrons, are distributed in energy according to a formula due to Cranberg *et al.*:¹

$$N(E) = 0.453e^{-E/0.965} \sinh(2.29E)^{1/2}$$

where E is the neutron energy in million electron volts and $N(E)$ is the fraction of all prompt neutrons produced per unit energy interval about E . The most probable prompt neutron energy is $\frac{1}{2}$ MeV and the mean energy is $2\frac{1}{2}$ MeV. In the range of 4 to 14 MeV, the fission spectrum can be approximated by a simple exponential form also due to Cranberg *et al.*:

$$N(E) = 1.75e^{-0.766E}$$

Note that for high energies, the yield decreases strongly with increasing energy.

Delayed Neutrons. In addition to the neutrons released instantaneously as described in the previous section, neutrons are released in the radioactive decay of some of the fission products. These neutrons are given off from a set of isotopes which decay with half-lives varying from 0.18 to 54.5 seconds. The fraction of all neutrons produced by the fission process which are "delayed" is 0.0029 for U-233, 0.0067 for U-235, and 0.0021 for Pu-239.² Since in addition they are of lower energy than fission neutrons, they are not usually of great consequence in reactor shielding. In the case of circulating-fuel reactors such as the Molten Salt Reactor Experiment at Oak Ridge, however, they are of great importance since their presence requires that the heat exchanger be shielded as a neutron source. Furthermore, activation of the coolant by these neutrons must be considered.

Prompt Fission Gamma Rays. At the instant of fission, one or more gamma rays are given off immediately, having on the average a total energy of about 7.2 MeV per fission event, the photons being distributed in energy approximately according to the following exponential:³

$$\Gamma_p(E) = 8.0e^{-1.10E} \text{ MeV}^{-1}$$

This formula fits the data within 40 per cent between 1 and 7 MeV. The fit is only somewhat worse down to 0.4 MeV, below which the gamma rays have not been measured. Significant numbers of gamma rays are not observed above about 7.3 MeV.

Fission-product-decay Gamma Rays. Fission products are radioactive and most of them decay with gamma-ray emission. For times after fission less than about 200 seconds, the fission-product gamma-ray spectrum can be approximated by the formula:³

$$\Gamma_{fp}(E) = 6.0e^{-1.10E} \text{ MeV}^{-1}$$

For times greater than 200 seconds, the formula gives an overestimate of the region above 3.5 MeV.

Since most of the fission-product gamma rays are produced at short times after fission, however, the foregoing formula is adequate for an operating reactor, which means that for simplicity, the total of fission-product and prompt-fission gamma rays can be represented by a single formula:³

$$\Gamma(E) = 14e^{-1.10E} \text{ MeV}^{-1}$$

After a reactor has been shut down, fission-product gamma rays will continue to be given off. The total gamma-ray energy given off per second per fission at time t seconds after the fission event is given approximately by the Way-Wigner formula:⁴

$$\Gamma(E) = 1.5t^{-1.2} \text{ MeV/sec-fission}$$

where t is the time after fission in seconds.

Capture Gamma Rays. Neutrons captured in the reactor core, reflector, or shield produce capture gamma rays, which usually have a total energy of about 7 MeV per capture event. These usually comprise the single most important gamma-ray source, from the shielding viewpoint. Sometimes boron is added to a shield to suppress capture gamma rays by absorbing neutrons with emission of an alpha particle and (93 per cent of the time) one $\frac{1}{2}$ -MeV gamma photon.

Inelastic-scattering Gamma Rays. Neutrons of sufficiently high energy can be scattered inelastically so that the struck nucleus is left in an excited state from which it decays, usually at once, by gamma-ray emission. The gamma-ray photons so produced have total energy less than the kinetic energy of the neutron. They may be produced in heavy non-magic nuclei by both low- and high-energy neutrons, in light elements by high-energy neutrons only, and not at all in hydrogen.

Interaction Processes. Interaction processes are described in other sections in more generality. Here we discuss them from the point of view of shielding.

Neutron Interaction Processes. The three possible processes are elastic scattering, inelastic scattering, and absorption, the last including all processes in which neutrons become part of the nucleus and hence "disappear." Generally, elastic scattering is most frequent but least effective in attenuation; inelastic scattering is nearly as frequent for fast neutrons but much more effective; and absorption is very rare except for slow neutrons, but it is, of course, very effective.

Neutron total cross sections generally decrease with increasing neutron energy, so that the fastest neutrons are most penetrating. Since collisions slow neutrons down, succeeding collisions are more likely, so that penetration can be quite well described in terms of a first flight at the initial energy with a succeeding short migration. The "effective removal cross section," which is the equivalent pure absorption cross section that best describes the observed neutron attenuation, is equal to about $\frac{1}{3}$ of the total cross section

because of the reduced effectiveness of elastic scatterings in most elements. For hydrogen, $\frac{1}{3}$ is replaced by about $\frac{1}{2}$.

For a fission source, the more penetrating fast neutrons are also least populous at birth. This means that for thin shields the neutrons which penetrate are born at lower energies than for thick shields, which "filter out" the lower energies. For most reactor shields, the neutrons which penetrate are born at about 8 MeV. Figure 1 shows the effective removal as well as the total (at 8 MeV) cross sections for the gamut of elements. The macroscopic cross section, Σ , divided by density ρ , is shown; this quotient is independent of material density.

Gamma Interaction Processes. The three dominant processes are: (1) photoelectric effect, (2) Compton scattering, and (3) electron pair production. The cross sections for these three processes vary with atomic number, Z , approximately as Z^5 , Z and Z^2 . As for the variation of the cross sections with energy, those for the photoelectric effect are generally greatest for low energies; those for the Compton effect vary similarly, but not nearly so strongly; and those for pair production increase strongly with increasing energy. For shielding purposes, (1) and (3) may be treated as absorption whereas (2) is a scattering with energy reduction. It follows from the foregoing that elements of large Z , such as Pb, are best for low- (<1 MeV) and high- (>6 MeV) energy gamma rays. For low Z elements (such as those in ordinary concrete), the Compton effect dominates for all but the lowest-energy gamma rays and even for high energies it dominates at the minimum in the total cross section (~ 3.5 MeV in Pb). Since the Compton effect cross section varies proportionally to Z , which is roughly proportional to material weight, the effectiveness of a gamma-ray shield commonly varies proportionally to the product of its thickness and density. Hydrogen (for which Z/A is at least twice as large as for any other element) is a special case. It would be the best shield on a weight basis for medium gamma-ray energies if its low density were not important.

Attenuation Calculation. Calculating the attenuation of a shield consists in calculating the effect outside a shield of radiation emanating from a region inside. For a point gamma-ray source, dose rate is given simply by:

$$D(R, t, E) = \frac{SB(\mu t) e^{-\mu t}}{4\pi R^2} \cdot \int E$$

where

S = source strength, photons emitted per unit time,

R = separation distance between source and point at which flux is calculated,

μt = number of mean free paths (mfp) of the radiation on a straight-line path along R

$B(\mu t)$ = buildup factor, the ratio of dose rate due to all photons to that due to particles which have not been scattered in traversing the medium,

FIG. 1. Total and removal cross sections (in square centimeters per gram) for all elements vs their atomic weight.

f = the dose rate per unit energy flux of photons as emitted by the source,
 E = energy per source photon in million electron volts.

For a single material, t would be the thickness traversed (in centimeters), and μ would be the total attenuation coefficient (cm^{-1}). For many layers, μt would be the sum of these factors for each layer. The total attenuation coefficients, dose factors f , and buildup factors for gamma rays passing through lead are given in Table I. Thus, for example, the dose at 70 cm from a 100-curie ($100 \times 3.7 \times 10^{10} \text{ sec}^{-1}$) source of 1.0-MeV gamma rays in a lead box shield (strictly, a spherical shell container) of wall thickness 10 cm is

$$D(70, 10, 1.0) =$$

$$\frac{100 \times 3.7 \times 10^{10} \cdot 3.19 \cdot e^{-7.73} \cdot 1.73 \times 10^{-6} \cdot 1.0}{4\pi \cdot (70)^2} \quad \text{rad/hr}$$

$$= 1.46 \times 10^{-1} \text{ rad/hr}$$

$$= 146 \text{ mrad/hr}$$

Neutron attenuation is more difficult to calculate because of the much less regular variation of cross

sections with energy and the greater variety of possible interactions. Simple estimates of the dose rates outside thick concrete shields can be obtained by use of the formula

$$D(R, t, E) = \frac{S e^{-\Sigma_r t} F}{4\pi R^2}$$

where

Σ_r = macroscopic effective removal cross section of the concrete used, calculated from the data of Fig. 1 (cm^{-1}); for ordinary concrete, $\Sigma_r \approx 0.086 \text{ cm}^{-1}$;

F = dose rate, rem/hr, per unit flux at the source energy; for a fission source and a thick shield, F is the same as that for neutrons at about 8 MeV; roughly, for $1 < E < 10 \text{ MeV}$, $F \approx 1/7000 \text{ rem/hr per neutron/cm}^2 \text{ sec}$;

S = source strength, neutrons/sec.

RECTIFIERS

Rectification (Electric). Energy is most conveniently transmitted and distributed by means of galvanic electric currents in metallic conductors (see CONDUCTIVITY, ELECTRICAL). In this form energy is easily transported with very low losses, easily accessible, and easy to control (see ELECTRIC POWER GENERATION). Transmission by electric current may also communicate intelligence, such as images, electroacoustic signals or counting pulses. Most human activities depend on some form of electric energy transport or distribution, such as power, telephone, radio, television, and most control functions.

Generators of electric energy from other physical forms normally utilize a mechanical intermediary (involving rotation or harmonic oscillation) followed by an electromagnetic generator. The output current is then equally alternating in both directions, it can thus be transformed to any desired current and voltage level. Alternating current is ideal for generating and transporting energy alone because no net electronic or electrolytic charge or material transport is required. On the other hand, in usage, whenever electrical energy is stored in batteries, energizes vacuum tube amplifiers, or is used for electrochemical separation or particle acceleration, the permanent and irreversible transport of charges is mandatory, hence a direct current is needed.

Rectifiers provide the physical means which achieve electric rectification, comprising all the elements which connect a complete ac circuit to a complete dc circuit, without being part of either (see Fig. 3). One rectifier may consist of a plurality of rectifier diodes, their mode of interconnection is called a *rectifier circuit*.

Rectifier Diodes. These are unilaterally conducting component devices with two terminals, similar to resistors because they are passive (i.e., not generating electric energy) and nonreactive (i.e., not able to store electric energy). The difference is in their being essentially nonlinear (whereas resistors are linear), their differential resistance varying over a very wide range, depending only on the direction and magnitude of the current through the device, i.e., they are not time-dependent (see Fig. 1).

Rectifier Switching. Rectification implies the concept of switching, i.e., introducing a circuit element which has a resistance which varies instantaneously over such a wide range that it may (mathematically) be considered as a discontinuity.

Example: Semiconductor diode (see Fig. 4)

Circuit impedance: 20 ohm

Diode forward resistance: 0.028 ohm 1/700 of circuit

Diode reverse resistance hot: 500,000 ohm - 25,000 times circuit.

Controlled Rectifiers (Fig. 2). Controlled rectifiers are similar to rectifier diodes, except that they have two states of forward conductivity: forward blocking (same resistance characteristic as in the reverse direction, which is the same as in a diode) and forward conducting (same as in a diode). A control element (gate, grid) allows switching from the forward blocking to the forward conducting state. This control is very rapid and requires very little energy. Hence, the rectifier output can be controlled with a high amplification and with high speed. Gas tube controlled rectifiers are thyatrons. Semiconductor controlled rectifiers (SCR) also known as thyristors.

Electronic Rectifier. Vacuum Tube (Diode, Triode, etc.). Electronic rectifiers are based on the Edison effect (see ELECTRON TUBES, ELECTRONICS, THERMOIONICS). Thermally emitted electrons from a hot metal oxide cathode are propelled across a short gap in high vacuum to a cold metallic anode. The high velocity of thermal electrons and the absence of a gas, generating positive ions, assure ideal conditions for electric rectification, i.e., a flow of pure electrons. Because of their high speed, the high-frequency response is very good. The potential field of the driving voltage accelerates the electrons, hence the rectifier is

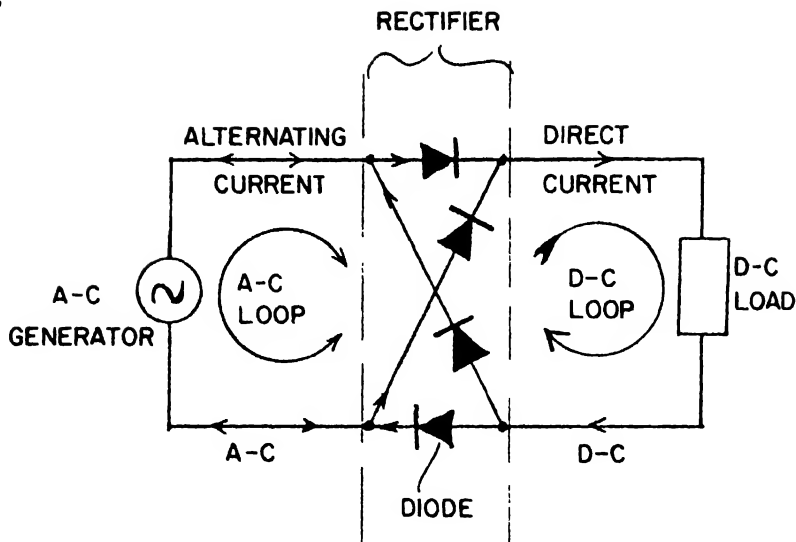

FIG. 3. Rectifier circuit: single-phase bridge. Four rectifier diodes are connected together to achieve full rectification of both (negative and positive) waves of a single phase alternating current. The alternating current flowing in the closed loop (ac circuit) on the left-hand side is converted into a direct current flowing in the closed loop (dc circuit) on the right-hand side.

essentially a linear resistor in the forward direction and a good insulator in the reverse direction. The applications of the vacuum tube are far beyond the scope of simple rectification. All the grid- and beam-controlled tubes are also rectifier diodes, although generally not defined as such. This is because the resistance changes (see MODULATION) in the current-carrying direction are technically and economically much more important.

Thyratron. Rectifier tubes containing a low-pressure gas instead of a vacuum have the property that the resistance in the current-carrying stage is very low but not linear, as in a vacuum tube. This makes the device useless for variable resistance control (amplification), but much more efficient for rectification; a major resistance in the current flow direction is eliminated. This reduction of resistance is caused by impact ionization of the gas, hence the thyratron responds less rapidly than the vacuum tube. The ionized gas is usually a pure element (e.g., mercury, hydrogen, krypton) to avoid chemical reactions between ions and electrodes. Current is carried both as positive ions and negative electrons. Thus, reversing the voltage on the gap results in a definite period of current reversal (ion sweep-out). This severely limits the useful operating frequency. A control grid allows one to select the time at which the thyratron becomes conductive ("firing"). Once conduction is initiated, the grid field is neutralized by the ionized gas, hence grid control has no effect (see Controlled Rectifier above).

Excitron (Mercury-arc Rectifier). This is similar to the thyratron, except the cathode is a pool of liquid mercury. An arc is sustained between the cathode and an exciting anode; conduction to the

main anode is controlled both by anode voltage and a control grid.

Ignitron. Replacing the heated solid cathode of a diode by a pool of liquid mercury gives an ignitron. To initiate conduction, a localized spot on the liquid surface (cathode spot) is forcibly overheated (ignited). Selecting the firing time (controlled rectifier) is achieved by energizing an ignitor which creates a cathode spot at a definite time. Ignitors are silicon carbide rods dipping into the mercury; subjected to a brief current pulse, a surface arc occurs at the mercury-silicon carbide interface. The liquid is locally driven to a very high temperature by forced electron emission and ion impact, resulting in violent evaporation and ionization of the mercury. Once conducting, the ignitron has the properties of a gas-filled tube (thyratron); it also requires the same deionization time and ion sweep-out current. Excess mercury vapor precipitates on the cold walls of the tube, flowing back into the liquid cathode. The ignitron is particularly applicable to very high power. It presents the advantages of high efficiency, high reliability and small size.

Semiconductor Rectifier. Crystallized semimetals (such as selenium, copper oxide, germanium or silicon) and some organic compositions can be used to make devices which rectify electric currents (see SEMICONDUCTORS and TRANSISTOR). Semiconductors carry current by excess electrons or electron vacancies (carriers) moving in the solid crystal lattice. The transfer of charges is very rapid and driven by very small potential differences. The polarity of a semiconductor is not determined by the material itself but by relatively few impurity nuclei ("doping") substituted in the crystal. Impurities (compared to the base material) have either an excess (*n*-type,

Diode characteristics in forward and reverse avalanche direction are essentially in the direction of constant voltage, whereas in reverse blocking they are in the direction of constant current.

negative, conducting by "electrons") or a deficiency (*p*-type, positive, conducting by "holes") of nuclear charges and hence electron shells. In the rigid lattice, the nuclei and normal electron shells are immobile. Excess or defect carriers are freely mobile. The density of these majority

carriers is determined by the relative content of impurities in the crystal. The background of the lattice with its mutually neutralizing nuclei and electron shells does not contribute to the conduction or to the distribution of potentials.

Semiconductors conduct both by majority

carriers (e.g., holes in *p*-type), and minority carriers (e.g., electrons in *p*-type) if such are injected by a junction with the opposite polarity material, e.g., majority carrier electrons coming from *n*-type material injected into *p*-type (see TRANSISTOR). Injected minority carriers are ultimately trapped and recombined with majority carriers; however, they transfer a major quantity of charge from one zone to another, depending on the "lifetime" (see SEMICONDUCTOR) of these minority carriers.

Semiconductor Rectifier Diodes (Fig. 1). They contain one thin, flat wafer consisting of a single crystal (e.g., silicon). The wafer is brazed to metallic electrodes (anode and cathode) on its two opposing flat sides. The rim of the wafer is insulated (by oxidation, insulating resin or fused glass). Within the wafer, a junction is established by heavy doping with *p*-type impurities on its anode face and *n*-type impurities on the cathode face. The junction consists of an intermediate, thin, flat zone in which the density of both *p*-type and *n*-type dopants is very low.

Applying a forward bias (P-positive, N-negative) to the device injects majority carriers from both zones through the junction into the opposite zone. Attracted by the opposite potential, they effect a total transfer of available charges; i.e., a current flows with only a low driving potential difference. An unlimited number of carriers can flow across the small potential (energy level) barrier between the zones, carriers are replenished by metal-to-semiconductor brazed joints on both faces of the wafer.

Reversing the bias at the junction (N-positive, P-negative) reverses the flow of carriers. Majority carriers from both zones are displaced away from the junction, a potential wall is created by depleting the crystal of its mobile carriers. The immovable charges of the lattice-bound nuclei which are now uncompensated by the displaced mobile charges, create a high potential wall. A very small reverse current flows, sustained only by the thermally generated minority carriers of both zones which are swept across the junction. When applying a very high potential (e.g., 1000 volts), these highly accelerated carriers generate more carriers by avalanche multiplication due to impact with the lattice; above a certain voltage, so many carriers are generated that the reverse characteristic remains at a constant voltage at any current level. As Fig. 4 shows, semiconductor diodes have a very low forward voltage drop (e.g., 1 volt) and the forward resistance is not constant but decreases with increasing current. The reverse current is negligibly small, except at very high voltage where the reverse resistance is negligible.

Varying the semiconductor material (mainly germanium and silicon), the impurity content, the distribution of impurities across the junction, the area of the junction, and its peripheral configuration (planar, mesa, cut wafer) allows for a multitude of possible designs, each preferred for certain applications. Silicon wafers with diffused impurities (e.g., boron and phosphorus) are

used for high-power, low-frequency rectifier diodes. Planar junctions on the surface of a solid wafer, in which the impurities are diffused under a layer of protective oxide, give diodes with good high-frequency and low-noise response. Junctions are also made by recrystallizing silicon from an alloy melt (alloyed junctions) or by epitaxially depositing pure silicon, with measured impurities, from the vapor phase upon a solid wafer.

Semiconductor Controlled Rectifiers (Fig. 2). Similar to transistors (rather than diodes) they consist of four layers of semiconductor material forming three closely adjacent junctions (against two in a transistor). Only three layers are connected to outside electrodes. Figure 2 is an example: Reverse bias (e.g., anode negative) blocks the flow of current similar to a diode between anode layer 1 and *n*-type intermediary layer 2. Forward bias (e.g., anode positive) blocks the flow of current similar to a diode between *p*-type gate layer 3 and *n*-type layer intermediary 2. Initiating a current between gate 5 and cathode 4 injects electrons into the gate layer 3; these are attracted into the adjacent reverse biased junction (3-2) where they attract and multiply due to (forward current) carrier injection by the two outer junctions (1-2 and 3-4). Counter-flow of opposite carriers through the same junction results in a very low voltage drop.

Reverse and forward blocking characteristics are similar to diode reverse characteristics (see Fig. 4). Forward conducting characteristics are similar to diode forward characteristics.

Mechanical Rectifier. A coil of wire rotating in a magnetic field generates an alternating voltage; if the ends of many similar coils are connected to "commutator bars" (arranged on a cylindrical commutator), the output of two stationary brushes contacting the bars is a direct current. This dynamo is of historic and economic significance. Trial-and-error improvements have made this combination of rotating machine and mechanical rectifier an efficient and economic system. Mechanical rectifiers separated from the moving coils (i.e., a commutator driven by a synchronous motor) are workable but less reliable (because subject to wear) and less economic than other rectifiers.

Electrolytic Rectifier. Some electrolytic batteries can serve as rectifiers because of the rapid and thorough polarization of one of the electrodes, whereas the other electrode may carry the current rather easily. The system is permanently changed by the flow of current; hence, it is not reliable or economical. Its speed of response is low, depending on the slow diffusion of ions in the electrolyte.

REFLECTION

If a perfectly smooth and flat interface exists between two homogeneous media, the ratio of the reflected to the incident intensity of light striking the interface is called the *reflectivity*. A real surface however, is not ideally smooth and undistorted so that the situation is complicated by surface conditions such as films, roughness, and disorder in the crystal lattice at the surface introduced by the polishing process. The measured ratio is thus usually termed the *reflectance* to distinguish it from the former more- or less-idealized situation.

The reflectivity of a material is intimately connected with its band structure.¹ In a single atom, the electrons surrounding the nucleus can have only certain discrete energies. In a solid or liquid, neighboring atoms interact with each other changing these discrete energy levels into energy bands. The energy band structure depends not only on the type of atoms involved but also on the interatomic spacing, and hence in a crystalline material on the lattice structure. In a noncrystalline solid or in a liquid, the correlation function takes the place of the crystalline lattice. The highest occupied energy band may be completely filled with electrons, as in the case of a dielectric or semiconductor, or only partially filled, as for a metal. If the band is not completely full, electrons may absorb energy from the incident light beam and be raised to higher energies in the band, thus affecting the reflectivity of the material. These *intraband* transitions of the conduction electrons, or, in the case of a nearly filled band, holes (the absence of electrons), largely determine the reflectivity of metals and some semiconductors in the infrared region of the spectrum. At shorter wavelengths, the light has sufficient energy to raise the electrons from one energy band to another, and the reflectivity is then largely determined by these *interband* transitions. At still shorter wavelengths, usually in the vacuum ultraviolet, the energy in the incident light beam can set the conduction electrons into collective oscillation so that a plasma resonance occurs in the reflectivity spectrum.

In dielectric materials, where the occupied band having the highest energy is completely filled and the gap between allowed energy bands is large, the energy in the incident light beam cannot be absorbed either in intraband transitions or, except at very short wavelengths, in interband transitions. Such materials are therefore often transparent over an extended wavelength region in the ultraviolet, visible and near infrared, and have a nonzero reflectivity in this wavelength region only because of the difference in the speed of light in the material and in the surrounding medium. However various types of imperfections, termed F centers, M centers, etc., may exist in the lattices of crystalline materials, and electrons trapped in such centers can strongly absorb certain energies, thus affecting the reflectivity. In the intermediate and far infrared, dielectrics and many semiconductors absorb because the

incident light excites vibrations in their crystal lattices. Since the frequencies of these lattice vibrations are quantized, this so-called phonon absorption results in maxima in the reflectivity spectra, termed *restrahlen* bands.

Other mechanisms also contribute to the reflectivity. Some which should be mentioned are transitions between a localized impurity level and an energy band, absorption by a bound hole-electron pair or exciton, and indirect or phonon-assisted interband transitions.

Electromagnetic Theory. The reflectivity of any material can be calculated from electromagnetic theory^{2,3} if the optical constants of the material are known. This theory, which is based entirely on Maxwell's equations, is phenomenological in that it does not attempt to explain why materials behave as they do, but rather sets forth relationships which exist between various properties of the material. In order to calculate the reflectance of a material from this theory, the two optical constants, n and k , must be known. The index of refraction n is equal to the ratio of the phase velocity of light in vacuum to the phase velocity in the material. The extinction coefficient k is equal to $\lambda/4\pi$ times the absorption coefficient of the material and is thus a measure of the fraction of light absorbed by a unit thickness of the material. These parameters, which are frequently combined into the complex refractive index $\tilde{n} = n - jk$, arise in the solution to the wave equation and completely describe all the optical properties of the material.

The equation for the propagation of an electromagnetic wave can be obtained directly from Maxwell's equations, and in Gaussian units can be written

$$\nabla^2 \mathbf{E} = \frac{\epsilon}{c^2} \frac{\partial^2 \mathbf{E}}{\partial t^2} + \frac{4\pi\sigma}{c^2} \frac{\partial \mathbf{E}}{\partial t} \quad (1)$$

where ∇^2 is the Laplacian operator $\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$, \mathbf{E} the electric field strength of the traveling

wave, t the time, c the velocity of light and ϵ and σ the dielectric constant and conductivity of the material, respectively, at the frequency of the wave. The solution representing a plane wave traveling in the z direction is

$$E = E_0 e^{j\omega(t - nz/c)} \quad (2)$$

where $\omega = 2\pi\nu$ is the angular frequency of the wave, E_0 the amplitude, and \tilde{n} the complex refractive index. By matching E_0 and its first derivative on either side of a smooth, plane interface between a transparent material of index n_0 , the medium of incidence, and a second material of index \tilde{n}_1 , one can obtain r , the ratio of the reflected to the incident amplitude, called the *amplitude reflection coefficient*:

$$r = \frac{\eta_0 - \tilde{\eta}_1}{\eta_0 + \tilde{\eta}_1} \quad (3)$$

where η_0 and $\bar{\eta}_1$ are the effective indices. At normal incidence, $\eta_0 = n_0$ and $\bar{\eta}_1 = \bar{n}_1 = n_1 - jk_1$.

At non-normal incidence, Snell's law may be used to determine the angle of refraction ϕ_r corresponding to a given angle of incidence ϕ_i . For the case when both materials are nonabsorbing, Snell's law states

$$\frac{\sin \phi_i}{\sin \phi_r} = \frac{n_1}{n_0} \quad (4)$$

It is also necessary to specify the state of polarization of the incident light. Since \mathbf{E} is a vector quantity, it is always possible to resolve it into two components, the so-called p and s components, polarized parallel to and perpendicular to the plane of incidence (the plane containing both the incident beam and the normal to the surface). There are then two effective indices, η_p and η_s , for each medium at a given angle of incidence. For nonabsorbing materials they are defined as

$$\eta_s = n \cos \phi \quad (5)$$

$$\eta_p = \frac{n}{\cos \phi} \quad (6)$$

where ϕ is the angle of incidence or refraction in the medium of index n . In the medium of incidence, ϕ becomes ϕ_i while in the second medium, ϕ becomes ϕ_r . If the second medium is absorbing ($k \neq 0$), $\cos \phi$ becomes complex, making η_s and η_p also complex. They may then be most easily calculated from the following expressions:⁴

$$\bar{\eta}_1 = A - jB \quad (7)$$

$$\eta_p = C - jD \quad (8)$$

where

$$A^2 - B^2 = n_1^2 - k_1^2 = n_0^2 \sin^2 \phi_i \quad (9)$$

$$AB = n_1 k_1 \quad (10)$$

$$C = A \left[1 + \frac{n_0^2 \sin^2 \phi_i}{A^2 + B^2} \right] \quad (11)$$

$$D = B \left[1 - \frac{n_0^2 \sin^2 \phi_i}{A^2 + B^2} \right] \quad (12)$$

The *intensity reflection coefficient* or *reflectivity* R , defined as the ratio of the intensities of the reflected and incident light, is obtained by multiplying the amplitude reflection coefficient of Eq. (3) by its complex conjugate. At normal incidence for an absorbing material

$$R = \frac{(n_1 - n_0)^2 + k_1^2}{(n_1 + n_0)^2 + k_1^2} \quad (13)$$

At non-normal incidence, the expressions for R_s and R_p for absorbing materials become quite complicated. However, for nonabsorbing materials

$$R_s = \frac{\sin^2(\phi_i - \phi_r)}{\sin^2(\phi_i + \phi_r)} \quad (14)$$

and

$$R_p = \frac{\tan^2(\phi_i - \phi_r)}{\tan^2(\phi_i + \phi_r)} \quad (15)$$

Equations (14) and (15) are the intensity expressions for Fresnel's equations. From Eq. (15) it is seen that when $\phi_i + \phi_r = 90^\circ$, $R_p = 0$ so that all of the reflected light is polarized in the s direction. The angle of incidence for this case is called the polarizing angle and is given by

$$\tan \phi_i = \frac{n_1}{n_0} \quad (16)$$

A plot of the reflectivity R_p and R_s as a function of angle of incidence is shown in Fig. 1(a) for a transparent material in air and in Fig. 1(b) for an absorbing material. Note that the R_p curve for the transparent material goes to zero while the R_p curve for the absorbing material does not.

The phenomenon of total internal reflection is important for transparent materials. If light passes from a more optically dense (higher index) medium of index n_0 to a less optically dense (lower index) medium of index n_1 , when $\sin \phi_i = n_1/n_0$, the angle of refraction in the less dense medium is 90° , as can be seen from Eq. (4). At larger angles of incidence, the light is totally internally reflected in the more dense medium. This method of obtaining a surface whose reflectivity is 100 per cent is widely used in optical instruments such as binoculars and periscopes, which contain internally reflecting prisms.

Whenever light is reflected from a surface, a change in phase occurs in the electric vector. For the case of a normal incidence reflection in air from a dielectric, the phase change β is 180° , while for a reflection in the more dense medium, β is 0° . When the reflection is from an absorbing material, β depends on the optical constants of the material,⁵ and $\tan \beta$ is given by the ratio of the imaginary to the real part of Eq. (3). If the medium of incidence is air,

$$\tan \beta = \frac{2k}{n^2 - k^2 - 1} \quad (17)$$

for a normal incidence reflection from an absorbing material with $\bar{n} = n - jk$. At non-normal incidence, the phase change on reflection is different for the p and s components. By a technique called ellipsometry,⁶ this difference in phase can be measured and used, along with other data, to determine the optical constants of a material. If a surface film is present, the phase difference between the p and s components can also be used to measure its growth. Films as thin as a monolayer or less can be detected in this way.

As was indicated at the beginning of this section, Maxwell's equations by themselves do not give sufficient information to relate the optical constants of a material to basic atomic parameters. A fundamental problem in the theory of the optical properties of solids is thus to supplement electromagnetic theory in such a way as to relate the optical constants of a material to nonoptical quantities which can be experimentally determined. If Eq. (2) is substituted into Eq. (1), one obtains the basic

FIG. 1. Graph of the reflectivity R_p and R_s as a function of angle of incidence for (a) a transparent material ($n = 2$) in air, and (b) an absorbing material ($n = 2$ and $k = 2$) in air.

equations relating the optical constants to the dielectric constant and conductivity measured at optical frequencies:

$$n^2 - k^2 = \epsilon \quad (18)$$

$$nk = \sigma/\nu \quad (19)$$

The problem is how to relate ϵ and σ to the dielectric constant and conductivity at zero frequency, ϵ_0 and σ_0 , or to atomic parameters such as the effective mass m^* , number of free carriers per cubic centimeter N , oscillator strength f , etc. A classical simple harmonic oscillator theory first proposed by H. A. Lorentz in 1880 has been successfully used to solve this problem for materials in which the absorption is caused by forced vibrations, while a companion classical theory proposed by P. Drude in 1901 has had similar success for materials where the absorption is due to free electrons and holes. Quantum mechanical treatments give rise to equations having the same form as the classical ones, but containing parameters whose values can be calculated rather than having to be empirically determined. Although these theories will not be discussed here, it can be pointed out that, to a very good approximation, the reflectivity of good conductors in the infrared region is given by⁷

$$R \approx 1 - \left[\frac{2\omega}{\pi\sigma_0} \right]^2 [(1 + \omega^2\tau^2)^{-1} - \omega\tau] \quad (20)$$

where the relaxation time τ is given by

$$\tau = \frac{m^*\sigma_0}{Ne^2} \quad (21)$$

and e is the electronic charge. At sufficiently long wavelengths, $\omega\tau \ll 1$ and the reflectivity is then given by the Hagen-Rubens relation

$$R = 1 - \left[\frac{2\omega}{\pi\sigma_0} \right]^2 \quad (22)$$

which may also be obtained directly from Eqs. (13), (18) and (19). Both Eqs. (20) and (22) are in good agreement with experiment.

Reflectance of Real Surfaces. In the preceding discussion, it has been assumed that there are two homogeneous media separated by a perfectly smooth and flat interface. In actual fact this situation does not occur, and it is necessary to consider how the deviation of real surfaces from this model affects the observed reflectance. Consider first the effect of surface roughness. For a perfectly smooth surface, all light is reflected at the specular angle, which is equal to the angle of incidence. At the other extreme, the angular dependence of light reflected from a perfectly diffuse reflector is independent of the angle of incidence, and Lambert's law then holds. This law may be stated

$$I_r(\theta) = I_0 \cos \theta \quad (23)$$

where I_0 is the total amount of light reflected per unit area normal to a perfectly diffuse plane reflector, and $I_r(\theta)$ that reflected per unit area at an angle θ to the normal. The reflectance of actual rough surfaces can be separated into "specular" and "diffuse" components, although the diffuse component usually does not obey Lambert's law exactly. If the heights of the surface irregularities are of the order of a wavelength or more, the reflectance is mostly diffuse

and depends strongly on the shape of the irregularities. However, if they are very small relative to the wavelength, most of the light is reflected specularly, the amount depending only on the height of the irregularities. For a random height distribution of surface irregularities, the specular reflectance at normal incidence R_s is given by⁸

$$R_s = R_0 e^{-(4\pi h/\lambda)^2} \quad (24)$$

where R_0 is the total reflectance of the surface, h the rms height of the surface irregularities, and λ the wavelength. R_s/R_0 is very sensitive to small values of h/λ . For example, if h is as small as 0.025λ (in the visible h would then be only one-half a microinch), the specular reflectance will be decreased by 10 per cent. The surfaces of mirrors used in optical instruments must thus be extremely smooth. Typically the rms roughness of such mirrors is less than 0.1 microinch and may be as small as 0.01 microinch.

The reflectance may also be affected by distortion of the crystal lattice at the surface caused by the polishing process. The amplitude penetration depth δ of light into an absorbing medium, given by

$$\delta = \lambda/2\pi k \quad (25)$$

is usually only a few hundred angstroms or roughly one microinch for metals or semiconductors in the intrinsic absorption region. On the other hand, lattice distortion introduced by optical polishing may extend for many thousand angstroms below the surface, so that the reflection takes place entirely in the disturbed surface layer. Fortunately, the lattice distortion on the surface can be nearly eliminated in many cases by using proper electropolishing techniques.⁹ Optical polishing can also produce changes in the reflectance of dielectrics and non-crystalline materials such as optical glass.

Changes in the energy band structure at the surface may also be caused by the crystal structure of evaporated films and by the presence of surface states in semiconductors. Both of these effects may influence the reflectance.

Finally, surface films can have a large effect on the reflectance. Although naturally occurring oxide films are important mainly in the ultraviolet, the reflectance may be substantially modified at any wavelength by overcoating the material with an evaporated thin film. Over a limited wavelength region, nearly any desired reflectance characteristic may be obtained in this way, and this technique is widely used in the optical industry.¹⁰ Perhaps the most familiar example of the application of a thin film is the antireflection coating on lenses. Others are the "cold" mirrors used in projection systems, the multilayer coatings which control the temperature of space vehicles by adjusting the reflectance of their outer surfaces, and finally the highly reflecting, low-absorbance dielectric multilayer films used with lasers.

REFRACTION

Refraction is the name given to the bending of a ray of light as it crosses the boundary separating two transparent media having differing propagation velocities.

In an attempt to discover a law connecting the directions of the light rays in the two media, W. Snell (1621) observed that there is a constant ratio between the lengths PB, PC of the two rays (Fig. 1) measured from the point of incidence P to any line such as DD' drawn parallel to the normal PN at the point of incidence. Later Descartes recognized that Snell's construction is equivalent to the mathematical expression

$$n \sin I = n' \sin I'$$

when I, I' are the angles of incidence between the two rays and the normal, and n, n' are the refractive indices of the two media respectively. The ratio of n' to n is called the "relative" refractive index of the two media.

FIG. 1. Illustrates Snell's construction.

Huygens' Wavelets. C. Huygens (1690) attempted to explain how a wave front progresses through a transparent medium. He supposed that each point on the wave front acts as an independent source of wavelets which expand at the velocity of light; the new wave front being the common envelope of all the little wavelets. After an instant of time, each point in the new wave front becomes a source of new wavelets, and so on. In a homogeneous isotropic medium the wavelets will be spheres, and the new wave front is a parallel curve to the original wave front. The light energy travels along *rays* which are everywhere perpendicular to the wave fronts. Malus (1808) showed that the rays and wave fronts remain always orthogonal as the beam of light from an object point traverses an optical system.

The absolute refractive index of a medium is defined as the ratio of the velocity of light in vacuum to its velocity in the medium. Because the presence of matter has the effect of making light travel more slowly, all absolute refractive indices are necessarily positive and greater than unity. Since the frequency of the light waves must remain constant, the wavelength in a dense medium will be less than the wavelength in vacuum in proportion to the refractive index of the medium. Refractive indices of liquids and crystals generally drop with increasing temperature; glasses are, however, often exceptional in this regard.¹

Refractive indices range from as low as 1.3 for some liquids such as water, through 1.5 to 1.9 for various types of glass, 2.5 for diamond up to as high as 4.0 for some materials (germanium) in the infrared. These exceptionally high indices are generally associated with complete opacity in the visible part of the spectrum.

Dispersion. It is found that the refractive index of all common materials rises with increasing frequency of the light (shorter wavelengths) leading to the phenomenon of *dispersion*. Because of this, a glass prism bends blue light more than red, thus spreading a ray of white light into its

component colors (Fig. 2). For a prism of very small angle A , the deviation angle D is given by

$$D = A(n - 1)$$

and the angular dispersion Δ between wavelengths a and b is given by

$$\Delta = A(n_b - n_a)$$

It has been customary to define the dispersive power w of a material as the ratio of the dispersion between the F and C Fraunhofer lines to the mean deviation, i.e., the deviation for the D Fraunhofer line. Thus

$$w = (n_F - n_C)/(n_D - 1)$$

The vacuum wavelengths of these lines are $C = 0.6563\mu$, $D = 0.5893\mu$, and $F = 0.4861\mu$. In the optical industry, the reciprocal of the dispersive power is, however, more generally used; i.e.,

$$V = 1/w = (n_D - 1)/(n_F - n_C)$$

This so-called " V -value" or "*Abbe number*" of optical glass ranges from about 25 for the densest flints up to about 70 for the lightest fluor crowns. Liquids and crystals are known in which the V -numbers range from about 16 (methylene iodide) to 95 (calcium fluoride).

FIG. 2. The dispersion caused by a prism.

Many attempts have been made to develop a formula connecting the refractive index of a material with the wavelength of the light. The best known and most comprehensive is that proposed by Sellmeier,² namely,

$$n^2 = a + \sum \frac{b}{c^2 - \lambda^2}$$

Here n is the refractive index corresponding to wavelength λ , while a , b , and c are constants. The constant c represents the center of an absorption band for which the refractive index becomes infinite; there are thus as many terms under the summation sign as there are absorption bands to be considered. For most transparent materials, it is sufficient to include one absorption band in the ultraviolet and one in the infrared.

This general formula may be reduced to a simpler form for a limited spectral range, some well-known simplifications being

$$n = a + b/\lambda^2 + c/\lambda^4 + \dots \quad (\text{Cauchy})$$

$$n = 1 + b/(c - \lambda) \quad (\text{Hartmann})$$

$$n = a + b/\lambda + c/\lambda^{7/2} \quad (\text{Conrady})$$

FIG. 3. Explanation of double refraction.

Recently Herzberger³ has shown that the refractive index of a transparent substance such as glass can be accurately represented by a four-constant formula of this type:

$$n = a + b\lambda^2 + cL + dL^2$$

where $L = 1/(\lambda^2 - 0.028)$.

Birefringence, or Double Refraction. Glasses, liquids, and some (e.g., cubic) crystals are *isotropic*, meaning that the velocity of light in the medium is independent of direction and the Huygenian wavelets are spherical. However, there are other crystals which are *anisotropic*. These have the property that a beam of light on entering the crystal is split into two perpendicularly polarized beams, one of which (the "ordinary") behaves normally, while the other (the "extraordinary") behaves abnormally in that the wave front is not perpendicular to the direction of propagation.

These two wave fronts can be explained by supposing that two Huygenian wavelets are formed at any point of incidence, the ordinary wavelet being spherical while the extraordinary wavelet is an ellipsoid, (Fig. 3).^{*} The advancing wave front is the common tangent to a row of wavelets, and the ray, or direction of travel, is found by joining the point of origin of the wavelet to the point of contact between the wavelet and the advancing wave front. The spherical wavelets thus yield a ray which is perpendicular to the wave front, but the ellipsoidal wavelets do not.

All anisotropic crystals possess either one or two directions ("optic axes") along which a ray of light is not divided into two. These are represented by the axes of symmetry of the ellipsoidal wavelets. Evidently if parallel light is travelling along an optic axis, the two advancing wave fronts will be parallel to one another and the two rays will coincide (see POLARIZED LIGHT).

^{*} R. W. Wood, "Physical Optics", 3rd ed., pp. 365-387, MacMillan, New York, 1943.

Refraction by an inhomogeneous Medium.

Suppose we have a parallel plate of material of which the refractive index varies laterally across the plate. A ray entering such a plate perpendicularly to its surface will suffer no refraction itself since the incidence angle is zero, but because there is a gradient of refractive index at right angles to the ray, the ray inside the plate will be bent towards the high-index region and will follow a curved path. This is readily seen if we remember that the ray will be perpendicular to the wave front and that each point on the wave front travels at a rate which is inversely proportional to the refractive index at that point. To determine the curvature of the ray inside the medium, we may refer to Fig. 4 in which CC' represents the surface of a nonhomogeneous medium, and $A'A$, $B'B$ represent two very close rays entering perpendicular to the surface. We shall suppose the velocity of light in the material to be v at A and $(v + dv)$ at B , the refractive indices being $(n + dn)$ and n respectively. Typical wavelets have been added at A and B , having radii AD and BE which are proportional to the velocities v and $(v + dv)$. Hence the refracted wave front is ED ; this intersects the surface at C , which is therefore the instantaneous center of curvature of the rays within the medium.

If r is the radius of ray AD ,

$$\frac{CA}{CB} = \frac{r}{r + dr} = \frac{AD}{BE} = \frac{v}{v + dv} = \frac{n + dn}{n}$$

FIG. 4. Bending of a light ray in an inhomogeneous medium.

Neglecting second-order infinitesimals this gives

$$\frac{1}{r} = \frac{1}{n} \left(\frac{dn}{dr} \right)$$

The curvature of the ray is, therefore, proportional to the rate of change of refractive index in a direction perpendicular to the ray itself.

This property of inhomogeneous media provides the explanation of mirages and also the well-known atmospheric refraction which makes celestial objects appear to be raised up by as much as half a degree for objects situated near the horizon.

REFRIGERATION

A refrigerator is an enclosure whose temperature is maintained substantially below the ambient temperature so that anything placed within may be kept cool. Early refrigerators, usually boxes immersed in cold running water or bathed in cold air from melting ice, were inconvenient and inefficient. Since the invention of vapor-compression and vapor-absorption refrigeration methods, mechanical refrigerators have become commonplace. More recently, the thermoelectric properties of semiconductors have been exploited and the magnetothermoelectric effects in semi-metals have been successfully employed in the laboratory especially at low temperatures.

A refrigerator may be considered a heat pump, for it extracts heat from a low-temperature region and delivers it to a high-temperature region, resembling a water pump which lifts water from a low-pressure region and delivers it to a high-pressure region. For household heating and air conditioning, such a system is so designed that, during the winter, heat is pumped from the earth or outside air into the building and, during the summer, heat is pumped in the reverse direction.

A refrigerator is rated by its *coefficient of performance*, which is defined as the ratio of the heat removed from the cold room per unit time to the net input power for operating the refrigerator; in symbols, $K \approx Q_1/P$. Vapor-absorption and thermoelectric refrigerators have lower coefficients of performance than vapor-compression refrigerators, but they have other

characteristics which are superior, such as quietness of operation or compactness.

Vapor-compression Refrigerator. This machine consists of a compressor, a condenser, a storage tank, a throttling valve, and an evaporator connected by suitable tubes with intake and outlet valves, as shown schematically in Fig. 1. The refrigerant is a liquid which partially vaporizes and cools as it passes through the throttling valve. Among the common refrigerants are ammonia, sulfur dioxide, and certain halide compounds of methane and ethane. Perhaps the most widely used of these in industry is ammonia and in the household dichlorodifluoromethane ("Freon-12"). Nearly constant pressures are maintained on either side of the throttling valve by means of the compressor.

FIG. 1. Vapor-compression refrigerator from "Thermophysics," by Allen L. King, San Francisco, W. H. Freeman and Co., 1962).

The mixed liquid and vapor, which is colder than the near-surround, absorbs heat from the interior of the refrigerator box or cold room and completely vaporizes. The vapor then is compressed to a smaller volume by the compressor, and its temperature and pressure increase. Finally, the refrigerant pours through the outlet valve into the condenser, where it cools down and condenses to the liquid phase. Here heat is transferred either to cold air blown across the cooling coils or to cold water flowing by the cooling chamber of the condenser.

Comparative tests have shown that the coefficient of performance of vapor-compression refrigerators depends very little on the nature of the refrigerant. Because of mechanical inefficiencies, its actual value may be well below the ideal value—ordinarily, between 2 and 3. If a household refrigerator in which "Freon-12" is the refrigerant is operated between -15 and

30°C, its ideal coefficient of performance equals 4.8, but its actual value may be only 2.8.

Vapor-absorption Refrigerator. In this system there are no moving parts; the added energy comes from a gas or liquid fuel burner or from an electrical heater, as heat, rather than from a compressor, as work. A simplified diagram of it is shown in Fig. 2. The refrigerant is ammonia gas, which is liberated from a water solution and transported from one region to another by the aid of hydrogen. The total pressure throughout the system is constant and therefore no valves are needed.

Heat from the external source is supplied to the generator where a mixture of ammonia and water vapor with drops of ammoniated water is raised to the separator in the same manner as water is raised to the coffee in a percolator. Ammonia vapor escapes from the liquid in the separator and rises to the condenser, where it cools and liquefies. Before the liquefied ammonia enters the evaporator, hydrogen, rising from the absorber, mixes with it and aids in the evaporation process. Finally, the mixture of hydrogen and ammonia vapor enters the absorber, where water from the separator dissolves the ammonia. The ammonia water returns to the generator to complete the cycle. In this cycle heat enters the system not only at the generator but also at the evaporator, and heat leaves the system at both the condenser and the absorber to enter the atmosphere by means of radiating fins.

No external work is done, and the change in internal energy of the refrigerant during a complete cycle is zero. The total heat $Q_a + Q_c$ released to the atmosphere per unit time by the absorber and the condenser equals the total heat $Q_k + Q_e$ absorbed per unit time from the heater at the generator and from the cold box at the evaporator; so $Q_e = Q_a + Q_c - Q_k$, and therefore the coefficient of performance is $K = Q_e / Q_k = \{ (Q_a + Q_c) / Q_k \} - 1$.

The vapor-absorption refrigerator is free from intermittent noises; but it requires a continuous supply of heat, as from bottled gas or electrical generators. Refrigerators of this type are found in camps and farm houses not supplied with commercial electric power and in apartment houses where unnecessary noise is prohibited.

Thermoelectric Refrigerator. This device utilizes the thermoelectric effect first observed by Peltier in 1834 (see THERMOELECTRICITY). He discovered that heat is either absorbed or generated at the junction of two different conducting substances depending on the direction of an electrical current through it. In 1838, Lenz performed an experiment which may be considered the forerunner of thermoelectric refrigeration. He succeeded in freezing a drop of water at a bismuth-antimony junction by means of an electric current in one direction and then in melting it by reversing the current. However, not until 1909-11 were the properties of a thermocouple for refrigerating devices clearly specified. Then Altenkirch showed that its two conductors should have not only high thermoelectric coefficients but also high electrical

conductivities to reduce Joule heating and low thermal conductivities to minimize heat losses by conduction. Although semiconducting materials such as lead telluride or bismuth telluride have been found satisfactory, refrigerators incorporating them have only limited application because as yet they cannot compete economically with conventional mechanical refrigerators.

A modern thermoelectric refrigerator unit consists of one or more stages of series-connected *n*-type and *p*-type semiconductors as illustrated in Fig. 3(a). The charge carriers are electrons in the *n*-type semiconductor and holes in the *p*-type semiconductor. When a difference of potential is maintained across AB with B at the higher potential, the negative electrons carry both kinetic and potential energy away from C as they move toward B in the *n*-type semiconductor; the positive holes do the same as they move away from C toward A in the *p*-type semiconductor. Since energy is carried away from C to AB in both arms of the thermocouple, junction C becomes cold and junctions AB become warm. Temperature differences as high as 75°C have been obtained in a single-stage unit. Higher temperature differences may be produced by arranging several stages in cascade as illustrated by the two-stage system in Fig. 3(b). A small seven-stage thermoelectric refrigerator system only 1.5 inches high, employing *n*-type and *p*-type bismuth telluride alloys, was built at the research center of the Borg-Warner Corporation. With water at 27°C as the heat sink, its cold junction dropped to -118°C.

The coefficient of performance of a multistage thermoelectric refrigerator is no greater than that of one of its units. Let the temperature difference between AB and C in Fig. 3(a) be ΔT . As a result of the Peltier effect, the cold junction cools down at the rate $\bar{\alpha}(T_m - \frac{1}{2}\Delta T)I$, where $\bar{\alpha}$ is the mean value of the Seebeck coefficients for the *n*-type and *p*-type semiconductors, T_m is the mean temperature of the thermocouple, and I is the current through it. But due to Joule heating and thermal conduction from the warm to the cold junction, the rate of cooling at C is only $Q_c = \bar{\alpha}(T_m - \frac{1}{2}\Delta T)I - \frac{1}{2}I^2R - \lambda\Delta T$, where the total resistance of the couple $R = (l_p/A_p\sigma_p) + (l_n/A_n\sigma_n)$ and its thermal conductance $\lambda = (A_pk_p/l_p) + (A_nk_n/l_n)$ in which A_p and A_n are the cross-sectional areas of the *p*-type and *n*-type semiconductors, l_p and l_n are their lengths, σ_p and σ_n are their electrical conductivities, and k_p and k_n are their thermal conductivities. The power supplied externally must just equal the total Seebeck and Joule terms, namely, $P = \bar{\alpha}I\Delta T + I^2R$. The coefficient of performance, therefore, is

$$K = Q_c/P = \frac{\bar{\alpha}(T_m - \frac{1}{2}\Delta T)I - \frac{1}{2}I^2R - \lambda\Delta T}{\bar{\alpha}I\Delta T + I^2R}$$

It reaches a maximum value when the products of the thermal and electrical conductances for the two semiconductors have the same value and when the electrical resistance at the junctions is much smaller than R . The optimum current

FIG. 2. Vapor-absorption refrigerator (from "Thermophysics," by Allen L. King, San Francisco, W. H. Freeman and Co., 1962).

FIG. 3. Thermoelectric refrigerator: (a) single stage, (b) two-stage cascade.

then is given by the equation $(IR)_{opt} = \bar{\alpha} \Delta T [1 + ZT_m]^{-1}$ where Z is the *figure of merit* of the thermocouple,

$$Z = \bar{\alpha}^2 / [(k_p / \sigma_p)^{-1} + (k_n / \sigma_n)^{-1}]^2$$

The maximum value of K can now be written in the form

$$K_{max} = \frac{T_m (\sqrt{1 + ZT_m} - 1)}{\Delta T (\sqrt{1 + ZT_m} + 1)} - \frac{1}{2}$$

Thus K_{max} increases with an increase in the figure of merit, reaching the value $(T_m - \frac{1}{2} \Delta T) / \Delta T$ for very large Z . This is the coefficient of performance for an ideal thermodynamic machine.

The thermoelectric refrigerator is useful where space is at a premium or where, for other reasons, mechanical refrigerators are inconvenient, such as for spot-cooling electronic devices and for portable ice-cube makers.

Thermomagnetic and Magnetothermoelectric Refrigerators. In 1958 O'Brien and Wallace suggested that by means of the Ettinghausen effect, one should be able to achieve cooling for refrigeration purposes (see HALL EFFECT AND

RELATED PHENOMENA). This suggestion has been followed up with some success at low temperatures and even with the heat sink near room temperature by a special "cascading" device. In 1962, Smith and Wolfe discovered that the thermoelectric figure of merit for bismuth-antimony alloys can be increased by means of a magnetic field and that this enhancement is especially pronounced at low temperatures. These effects may be applied advantageously to refrigeration at low ambient temperatures.

RELATIVITY

The basic ideas of modern relativity theory are largely due to one man: Albert Einstein (1879-1955). Both main branches of pre-Einstein physics had relied on an absolute space. To Newton this had served as the agent responsible for a particle's resistance to acceleration; to Maxwell—in the guise of an "aether"—it was

the carrier of electromagnetic stresses and waves. Relativity may be defined briefly as the abolition of absolute space. Special relativity (1905) abolished it in its Maxwellian sense, and general relativity (1915) in its Newtonian sense as well.

Before looking at the theoretical background of relativity, we shall mention some of its more striking practical implications. According to special relativity, for example, a rod moving longitudinally at speed v through an inertial frame is shortened, relative to that frame, by a factor $\gamma = (1 - v^2/c^2)^{-1/2}$, where c is the speed of light. This factor increases with v ; when v is as large as $\frac{1}{2}c$, γ is only 1.01, but at higher speeds it grows rapidly and becomes infinite when $v = c$. The rate of a clock moving at speed v is decreased by the same factor γ ; this is one aspect of the revolutionary prediction that time is not absolute and that, for example, after journeying at high speed through space, one could, upon return, find the world aged very much more than oneself. In fact, time and space become merged in a four-dimensional continuum in which neither possesses more absoluteness than, e.g., the x -separation between points in a Cartesian plane, which depends on the choice of axes. According to special relativity, time- and space-separations between events similarly depend on the choice of motion of the observer. The mass of a body moving at speed v is also increased by the factor γ and thus becomes infinite at the speed of light. This illustrates another prediction of the theory—that no body or physical effect can travel faster than light. But the single most important result of special relativity, in Einstein's opinion, was the equivalence of mass m and energy E according to the formula $E = mc^2$. Although the original impact of special relativity was mainly theoretical and philosophical, technology since 1905 has made such vast strides (atomic power, particle accelerators, Mössbauer effect, etc.) that today special relativity is one of the most practical and, at the same time, best verified branches of all physics.

The same cannot yet be said for general relativity, whose importance is still largely theoretical. But its ideas are hardly less striking. General relativity is the modern theory of gravitation. Like special relativity, it pictures the world as a four-dimensional space-time continuum, but according to general relativity this is curved by the matter present in it. Particles and light rays are postulated to move along geodesics ("straightest possible" curves) in this four-space, and all reference to an absolute three-space as the standard of non-acceleration has disappeared. It is one of the marvels of this theory that, starting from such utterly different premises it nevertheless reproduces within experimental accuracy almost all the well-established results of Newton's (inverse square) gravitational theory. In the few cases where its predictions differ to a presently measurable extent from Newton's (as for the advance of the perihelia of the planets), general relativity has been borne out by observation. Furthermore, general relativity first led to

the construction of many interesting cosmological models, such as closed and finite universes; it also implies the possibility of gravitational waves and thus the need to quantize the gravitational field.

The theoretical basis of special relativity is Einstein's *special principle of relativity* which asserts that *all* the laws of physics are equally valid in *all* inertial frames of reference. This is an extension to the whole of physics of a relativity principle which the laws of mechanics have long been known to obey. Newton, as Galileo before him, illustrated this with the familiar example of a ship, "where all motions happen after the same manner whether the ship is at rest or is carried forward in a right line." The reason why Einstein's principle was revolutionary is that the known properties of light seem to contradict it at once. In our quasi-inertial terrestrial reference frame (which was assumed to coincide more or less with Maxwell's aether), light is propagated rectilinearly in all directions at constant speed. This fact is often called the *law of light propagation*. The validity of this law in all inertial frames would imply, for example, that a light signal emitted at the instantaneous coincidence of two observers O and O' who are moving uniformly relative to each other, each fixed in an inertial frame, spreads spherically with both observers considering themselves to remain permanently at the center of the sphere. Hence a light signal would always recede from an observer at the same speed, no matter how fast he chases it. The adoption of the special principle of relativity together with the law of light propagation thus seems to lead to absurdities. But, in fact, this is not so: it merely leads to the downfall of the classical ideas of space and time. It was part of Einstein's genius to recognize that these ideas were dispensable.

Two types of argument can be made in support of Einstein's principle. The first is experimental: all experiments devised to discover the frame of Maxwell's aether, such as the well-known MICHELSON-MORLEY EXPERIMENT (1887), failed to give positive results, though such results would have been well within range of observability. The second argument is theoretical, and rests on the unity of physics. For example, mechanics involves matter, which is electromagnetically constituted; electromagnetic apparatus involves mechanical parts; and so forth. If, then, physics cannot be separated into strictly exclusive branches, it would seem unlikely that the laws of different branches should have different transformation properties.

Consider now two observers O and O' like the ones mentioned earlier, and a light signal emitted at their coincidence. If each observer remains at the origin of a Cartesian reference system and sets his clock to read zero when the signal is emitted, the events on the light front must satisfy both the equations

$$\begin{aligned}x^2 + y^2 + z^2 - c^2 t^2 &= 0 \\x'^2 + y'^2 + z'^2 - c'^2 t'^2 &= 0\end{aligned}\quad (1)$$

where primes distinguish the space and time coordinates used by O' from those used by O . Now suppose the two observers arrange their corresponding y and z axes to be parallel, and their x axes to coincide. In classical mechanics, with this configuration of reference systems, the so-called *Galilean transformation equations*

$$x' = x - vt, \quad y' = y, \quad z' = z, \quad t' = t \quad (2)$$

relate the corresponding coordinates of any event. But under this transformation, the two equations (1) are not equivalent. Einstein showed that for these equations to be equivalent, the transformation equations must necessarily be

$$x' = \gamma(x - vt), \quad y' = y, \quad z' = z,$$

$$t' = \gamma(t - vx/c^2) \quad (3)$$

where $\gamma = (1 - v^2/c^2)^{-1/2}$. These are the well-known *Lorentz equations* which constitute the mathematical core of the special theory of relativity. They replace equations (2), to which they nevertheless approximate when v is small. The most striking of equations (3) is the last. It implies that events with the same value of t do not necessarily correspond to events with the same value of t' , which means that *simultaneity is relative*. Setting $x = 0$ in that equation also shows that the clock at the origin of O goes slow by a factor γ in the frame of O' . But, setting $x = vt$, we see that the clock at the origin of O' similarly goes slow in the frame of O . Setting $t = 0$ in the first of equations (3), we see that a rod, fixed in the frame of O' along the x' axis, appears shortened by a factor γ in the frame of O ; this phenomenon too can be shown to be symmetric between the frames.

Another important property of equations (3) is that they leave invariant the differential quadratic

$$ds^2 = dx^2 + dy^2 + dz^2 - c^2 dt^2 \quad (4)$$

which leads to the possibility of mapping events in a four-dimensional pseudo-Euclidean *space-time* in which an absolute *interval* ds exists, and in which the language and results of four-dimensional geometry can thus be applied. For example, a uniformly moving particle is described simply by a straight line in this space-time.

Since Newton's laws of mechanics are invariant under the transformation (2) and *not* (3), it was necessary to amend these laws so as to make them "Lorentz invariant." It was found possible to do this by retaining the classical laws of conservation of mass and momentum but postulating that the mass of moving bodies increases by the factor γ , a fact amply borne out by modern particle accelerators. This led to the theoretical discovery of the equivalence of mass and energy—most spectacularly exemplified by the atomic bomb.

In contrast to Newton's theory, Maxwell's vacuum electrodynamics was compatible with Einstein's theory. Lorentz, independently of Einstein, but without realizing the full significance of his result, had already discovered equations (3)

as precisely those which leave Maxwell's equations invariant. In other words, Maxwell's equations already were "Lorentz invariant" and needed no modification. Nevertheless relativity has considerably deepened our understanding of Maxwell's theory. Other branches of physics, like kinematics, optics, hydrodynamics, thermodynamics, non-vacuum electrodynamics, etc., all underwent slight modifications to make them Lorentz invariant. Only Newton's inverse square gravitational theory proved refractory; several Lorentz invariant modifications of it were proposed but none were entirely acceptable.

Einstein eventually solved the gravitational problem in an unexpected way. He rejected Newton's absolute space as the cause of inertia on the grounds that "it is contrary to the spirit of science to conceive of a thing which acts but cannot be acted upon." His general theory of relativity ascribes to the space-time continuum discovered by special relativity the role of an inertial guiding field (free particles and light follow geodesics) but allows this field to be affected (curved) by the matter in it.

This extension was made possible by the so-called *principle of equivalence*. To Newton, an inertial frame was, primarily, the frame of "absolute space" in which the stars were assumed to be fixed, and, secondarily, any frame moving uniformly relative to absolute space. Thus an inertial frame exhibited its defining property, viz., that in it free particles move uniformly and rectilinearly (Newton's first law), only in the regions far from attracting masses. In 1907 Einstein changed this global definition to a local one: a local inertial frame is a freely falling non-rotating reference system. (The meaning of "local" is here determined by the extent to which the nonuniformity of the gravitational field is negligible.) Within the limits of each such frame Newton's laws of mechanics would be valid according to the classical theory; in particular, Newton's first law would be strictly satisfied. Now Einstein once again made the generalization from mechanics to the whole of physics. His principle of equivalence asserted that all the laws of physics are the same in each local inertial frame. It is these frames, therefore, which are the proper province of the special principle of relativity. Special relativity now becomes a local theory. In recompense, we need no longer go to the tenuous interstellar regions for its strict validity.

As we have seen, special relativity forces a four-dimensional metric structure [Eq. (4)] on the events within an inertial frame. By patching together the structures of all the local inertial frames, we obtain the structure of the world of general relativity. Locally, it can be regarded as flat. But it is evident that, if the very suggestive geodesic law of motion is to hold, the presence of matter must impress a curvature on this space-time. For example, the planets move in patently curved paths around the sun (in four-dimensions these are helicoidal rather than elliptical); for these paths to be geodesic, the space-time around

the sun must be curved. Just how matter curves the surrounding space-time is expressed by Einstein's field equations

$$G_{ij} = -\frac{8\pi G}{c^4} T_{ij} \quad (5)$$

which look deceptively simple. Technically, they represent ten second-order partial differential equations for the metric of space-time. This metric enters the 16 components of the "Einstein tensor" G_{ij} , of which only 10 are independent, for $G_{ij} = G_{ji}$. G is the constant of gravitation; T_{ij} is the so-called energy tensor of the matter, and its components represent a generalization of the classical concept of density.

The exact solution of Eq. (5) has been possible only in a limited number of physical situations. For example, in 1916 Schwarzschild gave the exact solution for the space-time around a spherical mass m (e.g., the sun):

$$ds^2 = (1 - a/r)^{-1} dr^2 + r^2(d\theta^2 + \sin^2\theta d\phi^2) - (1 - a/r)c^2 dt^2 \quad (6)$$

where $a = 2Gm/c^2$, r is a measure of distance from the central mass, t is a measure of time, and θ and ϕ are the usual angular coordinates. Note that when $m = 0$, Eq. (6) reduces simply to the flat space-time of Eq. (4), written in polar coordinates, and its geodesics would be straight lines (in space and time). But for Eq. (6), the geodesics in the plane $\theta = \pi/2$ are found to satisfy the equation

$$\frac{d^2u}{d\phi^2} + u = \frac{Gm}{h^2} + \frac{3Gmu^2}{c^2} \quad (7)$$

where $u = 1/r$ and h is a constant. This differs formally from the classical orbit equation only by the presence of the last term, which is very small. But as a consequence of that term, the solution of Eq. (7) is

$$u = Gmh^{-2}(1 + e \cos p\phi), \quad p = 1 + 3G^2m^2h^{-2}c^{-2} \quad (8)$$

instead of the classical solution which has $p = 1$. Now r is a function in ϕ of period $2\pi/p$ instead of 2π , and therefore the orbital ellipse precesses. For the planet Mercury, for example, the secular precession predicted is $42''$ (seconds of arc), and this agrees well with observation. In the space-time defined by Equation (6) one also finds that light-signals which pass close to the central mass are bent by an angle twice as big as that predicted on a simple Newtonian corpuscular theory of light; and again observations bear out the relativistic prediction. The third "crucial" prediction, which has also been verified observationally, is the reddening of the light received from the surface of very dense stars.

RELAXATION

By relaxation is understood the phenomenon that an observable time elapses between the moment when a system in equilibrium is subjected to a momentary change in condition and the moment when the system is again in equilibrium.

A good example of a system showing relaxation is an uncharged capacitor with a capacitance C connected in series with a resistance R , to which circuit a constant voltage U is applied at a time $t = 0$. The charge Q of the capacitor at time t is given by the differential equation

$$U = \frac{Q}{C} + R \frac{dQ}{dt} \quad (1)$$

the solution of which is:

$$Q = CU(1 - e^{-\frac{t}{RC}}) \quad (2)$$

Hence the charge Q does not follow the sudden change of U but shows an exponential increase towards the final value CU (see Fig. 1). The time $\tau = RC$ is referred to as the relaxation time of the system. Obviously τ governs both the rate of charging and the rate of discharge: if the capacitor with a charge Q_0 is shortcircuited via a resistance at the time $t = 0$, then the charge at time t is given by:

$$Q = Q_0 e^{-\frac{t}{\tau}}$$

Relaxation is met with in various fields of physics, e.g.:

(a) If a spring connected in parallel with a dashpot is suddenly loaded with a constant force, it will take some time until this system is again in equilibrium.

(b) If an electrically or magnetically polarizable substance is suddenly placed in a constant

electric or magnetic field, it will take some time until the electric or magnetic dipoles have orientated themselves in the field.

(c) If the irradiation of a phosphorescent substance is suddenly stopped, the phosphorescence does not cease immediately but continues for some time during which the intensity decreases exponentially.

An electrical analogy can be devised for all these cases. For instance, if in case (a) we substitute a voltage for the force, a charge for the displacement, the reciprocal of a capacitance for the spring constant f , and a resistance for the coefficient of friction η , we obtain exactly the differential equation [Eq. (1)]. The relaxation time τ will then be $\tau = \eta/f$, which quantity depends on temperature since as a rule η greatly varies with temperature. Generally, the relaxation times in electrically and magnetically polarizable media also vary with temperature.

FIG. 1. Q vs t .

If we subject a system having relaxation properties to a periodically varying change in condition instead of one sudden change in condition, some characteristics are revealed which are likewise typical of relaxation. Let us again take the RC circuit as an example, this time applying to it a voltage $U = U_0 \sin \omega t$. Solution of the differential equation [Eq. (1)] yields the following expression for the charge Q of the capacitor:

$$Q = \frac{CU_0}{\sqrt{1 + \omega^2\tau^2}} \sin(\omega t - \text{tg}^{-1} \omega\tau)$$

The charge has a component Q' which is in phase with the voltage applied and a component Q'' which is shifted 90° in relation to the voltage applied. Q' and Q'' , usually referred to as the real and the imaginary component of Q , respectively, are given by:

$$Q' = CU_0 \frac{1}{1 + \omega^2\tau^2}$$

$$Q'' = CU_0 \frac{\omega\tau}{1 + \omega^2\tau^2}$$

The variation of Q' and Q'' with $\omega\tau$ is shown in Fig. 2 where $\omega\tau$ has been plotted logarithmically in order to obtain symmetrical curves.

Q'' is a measure of the energy dissipated in the circuit per cycle; it has its maximum value at $\omega = 1/\tau$ and a negligibly small value at much higher and much lower frequencies.

Furthermore, Q'' reaches half its maximum value at $\omega = 3.73/\tau$ and $\omega = 0.27/\tau$ so that the half-width value $\Delta\omega$ of the Q'' curve expressed in angular frequency units is $3.46/\tau$. At $\omega = 1/\tau$, Q' just has half its maximum value.

Hence, by measuring Q' and Q'' vs frequency, we have various possibilities for determining the relaxation time.

If a dielectric solid is subjected to a periodically changing electric stress and the real (in-phase) and imaginary (out-of-phase) components of the dielectric constant of the substance are determined, curves will be found having a shape as shown in Figs. 2(a) and 2(b), from which the relaxation time can be determined. The mechanical relaxation time of an elastic solid can be determined in a similar manner.

In some cases, not one but several absorption peaks with the corresponding changes of the real component are found in this kind of experiment, from which it can be concluded that several relaxation mechanisms are involved. This phenomenon is frequently observed in polymers where the various components, such as short chains, long chains, cross-linked chains, etc., have

FIG. 2. Q' (a) and Q'' (b) vs $\log \omega\tau$.

different possibilities of moving and therefore have different relaxation times. There are also cases in which there is a more or less continuous distribution of relaxation times, and consequently, an absorption which is practically independent of frequency.

Since the above-mentioned electric circuit has no inductance (which corresponds to the masses of the particles in magnetic, electric and mechanical systems), there can be no resonance either.

As an example of a system having both resonance and relaxation properties, we will consider a substance containing magnetic nuclei, e.g., hydrogen nuclei, which at the time $t = 0$ is placed in a magnetic field H . In this substance a magnetic moment M is built up in the direction of H by the fact that the original random orientation of the magnetic dipoles of the nuclei changes under the influence of the magnetic field into a distribution of such a nature that a resulting moment M arises in the direction of the magnetic field. M is determined by an equation analogous to Eq. (2), namely:

$$M = M_0(1 - e^{-\frac{t}{T_1}})$$

where M_0 is the final value of M and T_1 is a relaxation time known as longitudinal or spin-lattice relaxation time, which is associated with the interaction between the magnetic dipoles and their surroundings.

Now, if the direction of the magnetic field is suddenly changed, M will make a precessional motion about the new H due to the fact that the resulting angular momentum J is coupled to the magnetic moment M of the nuclei via the relation $\gamma = M/J$ where γ is the magnetogyric ratio of the nuclei.

The angular frequency of the precessional motion is given by:

$$\omega = \gamma H$$

On behalf of the precessional motion, the magnetic moment M has not only a longitudinal component M_1 in the direction of the new magnetic field but also a transverse component M_2 at right angles to the new magnetic field. Whereas it would seem logical to expect that M_1 would increase and M_2 decrease exponentially with the relaxation time T_1 due to the relaxation mechanism, in reality this is not so.

Experiments have shown that M_2 decreases faster than the increase of M_1 so that apart from the longitudinal relaxation time T_1 there must also be a separate transverse relaxation time T_2 which invariably is smaller than or equal to T_1 . The existence of a T_2 besides T_1 can be explained by the fact that apart from the return of individual magnetic moments of the nuclei to the direction of H (which is characterized by T_1), it is also possible for these individual magnetic moments—which together form M —to continue their precessional motion along the same conical shell though getting out of phase by mutual interaction. In the latter case, M_2 decreases whereas M_1 remains unchanged.

Just as with nonresonating systems, periodically changing quantities can be successfully introduced in resonating systems. In the case of a substance containing magnetic nuclei, this is done by applying, beside a stationary magnetic field H_z in the z -direction, also a periodically changing magnetic field $2H_1 \sin \omega t$ in the x -direction. This is known as a nuclear magnetic resonance experiment. In this case, a periodically changing magnetization intensity is created in the x -direction whose real (in-phase) component M' and imaginary (out-of-phase) component M'' are given by:

$$M' = \gamma M_0 H_1 \frac{T_2^2(\gamma H_z - \omega)}{1 + T_2^2(\gamma H_z - \omega)^2 + \gamma^2 H_1^2 T_1 T_2}$$

$$M'' = \gamma M_0 H_1 \frac{T_2}{1 + T_2^2(\gamma H_z - \omega)^2 + \gamma^2 H_1^2 T_1 T_2}$$

where M_0 is the magnetic moment when no periodically changing magnetic field is applied.

These quantities can both be determined experimentally. Usually the experiment is done so that ω is maintained constant and H_z is slowly varied. In this case M'' is proportional to the energy absorbed by the system per unit of time.

The variation of $M'/\gamma M_0 H_1 T_2$ and $M''/\gamma M_0 H_1 T_2$ has been plotted against $T_2(\gamma H_z - \omega)$ in Fig. 3, it having been assumed that H_1 is so small that $\gamma^2 H_1^2 T_1 T_2$ is much smaller than 1. It will be seen that the curves differ considerably from those in

FIG. 3. Shape of the dispersion (a) and absorption (b) curves.

Fig. 2. The absorption curve has its maximum at the value $\gamma H_z = \omega$ which value has nothing to do with the relaxation times but only with the concurrence of the precessional frequency γH_z of the magnetic moment in the magnetic field H_z with the frequency of the periodically changing magnetic field. Hence it is clearly a matter of resonance absorption. The half-width value $\Delta\omega$ of the absorption curve, expressed in terms of a frequency, is $2/T_2$. The $M'/\gamma M_0 H_1 T_2$ curve is the curve of anomalous dispersion, which at $\gamma H_z = \omega$ has just the value 0, which is invariably found with resonating systems. With increasing values of H_1 both curves get wider and wider and the absorption curve eventually becomes 0 throughout. This phenomenon is called saturation. T_1 and T_2 can be calculated in principle from curves plotted for different known values of H_1 . Both relaxation times are very much dependent on temperature and on the phase of the substance under test.

The same phenomena are observed in the case of resonance of unpaired electrons, known as electron spin resonance.

Generally speaking, the investigation of relaxation times provides information on the surroundings of relaxing particles and thus can contribute to our knowledge about the structure of substances.

Furthermore, profound knowledge of relaxation times is essential in many instances to the control of physical processes (e.g., the creation of low temperatures by magnetic means) and physical techniques (e.g., the maser technique).

REPRODUCTION OF SOUND

History. In 1807 the British physicist Thomas Young designed the first device capable of making a graphic record of sound waves. His description of the principle of sound recording is as clear and valid today as it was then, and it may serve here:

"The situation of a particle at any time may be represented by supposing it to mark its path, on a surface sliding uniformly along in a transverse direction. Thus, if we fix a small pencil in a vibrating rod, and

draw a sheet of paper along, against the point of the pencil, an undulated line will be marked on the paper, and will correctly represent the progress of the vibration."

The recording stylus of Young's device had to be touched directly with the sound source. The "phonautograph" developed by Léon Scott de Martinville in 1856 was able to record sound from the air, via a horn, parchment diaphragm, and hog-bristle stylus. Both the Young and Scott devices made a helical trace on a rotating cylinder. Neither recording could be played back because the recorded trace was not deep or stiff enough to guide the vibrations of a reproducing stylus.

In April 1877, Charles Cros deposited with the French Academy of Sciences a sealed package containing the description of a complete record-reproduce system. Cros planned to use metal records photoengraved from an original tracing in lampblack, but never carried out his plans. In the fall of that year, Edison constructed a "phonograph" whose recording stylus made indentations on tinfoil wrapped on a pre-grooved cylinder. Although these indentations were partly deformed by the playback stylus, a weak, distorted, but intelligible version of the human voice could be reproduced.

Modern disc recording is closer to the Cros system than to Edison's; commercial recordings are stampings from a hardened mold. Virtually all original recordings for home use are first made on magnetic tape. They are then cut into a master disc made of a relatively soft material, lacquer, and end up as a metal stamper from which mass impressions can be made in a vinyl composition.

Modern Recording Systems. Current recording media include magnetic tape, transparent film, and grooved discs. The most widely used is the disc.

If the disc cutter head is fed with constant electrical energy over the frequency spectrum, it will produce constant average velocity in the recording stylus. Since the wave length of the recorded signal is doubled with each lower octave, constant stylus velocity would produce impractically large groove excursions in the bass range. Progressive bass attenuation is therefore introduced below a frequency which has now been standardized at 500 cycles, called the *turnover* frequency, in such an amount that the amplitude of groove modulation for signals below this frequency remains the same at a given power. A compensatory boosting of the bass frequencies must be employed in the playback amplifier.

A second problem in disc recording has to do with surface noise introduced by irregularities in the record material and picked up by the needle. The noise is distributed fairly evenly over the frequency spectrum on the basis of energy per cycle. Since each higher octave covers twice the number of cycles, this noise may be considered primarily a treble phenomenon (see NOISE, ACOUSTICAL).

The signal to the recording cutter is again

altered, this time by progressive treble boost. In playback, a compensatory treble attenuation is introduced which brings the recorded signal back to normal and at the same time significantly reduces the amount of surface noise. This system of recording *preemphasis* does not change the treble content of the final reproduced sound, but it increases the amplitude of the high-frequency groove modulations relative to the random surface irregularities in the recorded material.

These changes of frequency balance in the recorded signal are called *equalization*; the particular equalization curve is called the *recording characteristic*.

The Modern Disc Reproducing System. A pickup, also called a cartridge, traces the groove modulations through a needle or stylus, whose vibrations are converted to an electrical signal. The most common types of electrical generator employed in cartridges are the ceramic (piezo-electric), moving magnet, moving coil, and variable reluctance. It is the task of the cartridge to translate faithfully the wave forms of the groove into an electrical signal. Some of the problems in cartridge design have to do with the stiffness of the moving needle system, which tends to wear the record, and with the mass of the needle tip, which tends to resonate with the semi-elastic record material at high frequencies.

The turntable must revolve the record at a constant speed. Periodic variations in this speed are called *flutter* (the onomatopoeic term for very slow flutter is *wow*). Any noise introduced into the signal by the moving parts (via the pickup) is called *rumble*. A pivoted arm holds the cartridge in place over the record groove, with the vibration axis of the cartridge approximately tangent to the groove over the entire radius of the record.

The amplifier, which may be on one or more chassis, has two sections: the *preamplifier* and the *power amplifier*. The former is a voltage amplifier which performs the functions of input program selection, tone control, volume control, compensation for the frequency equalization introduced in recording, and voltage amplification of the input signal to the point where it can drive the power amplifier. The latter builds up the electrical signal power so that the signal is able to drive the loudspeaker or speakers.

An amplifier is a device whose output energy is greater than, but in the same form as, the input signal energy. The amplifier must therefore borrow energy from an outside source, normally the electrical power line. There are many types of basic amplifying devices. The two that are used almost universally in sound reproduction are the vacuum tube and the transistor.

The loudspeaker converts the electrical output of the amplifier into acoustical energy, usually through a vibrating diaphragm. The loudspeaker and the cartridge, because they are mechanical devices with their own resonances and characteristic behavior, are more intransigent to precise control by the input signal than electronic circuits.

A reproducing system is designed for minimum noise, distortion, frequency discrimination over the audible spectrum, and transient ringing; speakers must also have adequate treble dispersion.

Stereophony. Stereophonic sound is recorded on two separate channels from separate microphone inputs. Just as each lens of a stereoscopic camera takes a complete picture, each microphone channel picks up all of the sound, one from a right-oriented perspective and the other from a left-oriented perspective. When the two channels are played back through separate right and left speakers, the sense of the acoustical atmosphere of the concert hall is enhanced; a corollary of this is an increased clarity of inner melodic voices. The ability of the listener to determine the apparent position of different musical instruments is a less important part of the stereo effect.

In stereo disc recording, one channel is, in effect, recorded on the left groove wall, and the other channel on the right groove wall. The reproducing stylus must execute a complex motion containing both vertical and horizontal components in order to follow the modulations of both groove walls simultaneously. These complex movements are analyzed into two vectors by two separate generating elements, each at 45° to the vertical and on opposite sides. Each generating element produces the electrical signal for one channel.

The ultimate design goal of sound reproducing equipment is not to create "better" sound, but to efface the imprint of the equipment, so that the original musical quality is recreated.

RESONANCE

The phenomenon which scientists call resonance can be identified in many different physical systems of widely varying sizes. For instance, a father who pushes his small child on a swing finds that with each successive push the swing

goes higher. An astronomer who examines the spectrum of the sun notes the appearance of a series of dark lines superposed on the continuous red to violet band of colors. The solid state physicist who observes the amount of electromagnetic radiation transmitted through a waveguide at a particular microwave frequency finds it can be sharply reduced if certain materials are placed in the guide and a magnetic field is applied. All of these effects are examples of resonance, yet the actual physical mechanisms are different and the explanations require different analytical procedures depending on whether the system is governed by classical or quantum theory.

In the case of the father pushing the swing, the resonance can be explained as a direct consequence of Newton's laws of classical mechanics. In simple terms, it occurs when an outside agent (the father) pushes the system (swing with child) with a periodic force having the same frequency as the natural frequency of the system itself. The natural frequency is the frequency with which the system oscillates if it is displaced from its normal position of equilibrium and then released to swing freely back and forth. If the external push is timed so as to be exactly in step with the natural frequency, one can think of the swing as being steadily accelerated in its natural direction of motion. When the natural direction of motion changes at the end points of the path so does the push. Elementary kinematics then predicts that such a steady acceleration will cause both the displacement and the maximum velocity to increase continuously and eventually become very large. It is this extreme magnitude of displacement and velocity which is the most noticeable aspect of resonance in a mechanical system. However, less apparent visually, yet equally important, is the rate of energy transfer between the source and the system at resonance. The external agent transfers energy in the form of mechanical work to the system. At resonance, the average rate of this energy transfer per cycle becomes a maximum. This property of maximum rate of energy transfer is of great value when analyzing the effect of radiation on microscopic systems such as atoms and nuclei whose physical behavior must be explained by the laws of quantum physics rather than classical physics. In these systems as in mechanical systems a necessary condition for resonance is that the frequency of the radiation must match a frequency which is in some way associated intrinsically with the system. But here the coordinates of position and velocity are no longer suitable ones to use in describing the response at resonance. Nevertheless, the resonant system is still characterized by the general property that the rate of energy transfer into it is a maximum. In order to bring out the essential features of resonance involving both the behavior of position and velocity and the rate of energy transfer, it is simplest to examine a mechanical system consisting of a mass on a spring with frictional damping.

Resonance in a Simple Mechanical Oscillator. We begin with a mass M attached to a fixed point

by a spring with a force constant K and a damping resistance R . In addition the mass is acted upon by a periodic external force of frequency ν , $F = F_0 \cos 2\pi\nu t$. The displacement of the mass from its normal equilibrium position is represented by x . The acceleration d^2x/dt^2 of the mass M is determined by the resultant of these three forces, all along the x -direction: $-Kx$, the elastic restoring force; $-R(dx/dt)$, the damping force proportional to the instantaneous velocity dx/dt ; and the external force $F_0 \cos 2\pi\nu t$. Newton's second law of motion, which states that resultant force = mass \times acceleration, can be expressed by a second-order inhomogeneous linear differential equation:

$$M \frac{d^2x}{dt^2} + R \frac{dx}{dt} + Kx = F_0 \cos 2\pi\nu t \quad (1)$$

However, in order to discuss resonance it is first necessary to describe the behavior of the spring system when no external driving force is being applied. If the mass is displaced from its normal equilibrium position and then released, it will move in simple harmonic motion with the natural frequency ν_1 given by

$$\nu_1 = \frac{1}{2\pi} \sqrt{\frac{K}{M} - \frac{R^2}{4M^2}}, \quad \left(\frac{K}{M} - \frac{R^2}{4M^2} \right) \quad (2)$$

This result can be derived mathematically by setting the term on the right-hand side of Eq. (1) equal to zero thus making the equation homogeneous. It can be solved for $x(t)$ by standard methods (see references 1 and 2). The solution is:

$$x = Ae^{-\frac{R}{2M}t} \sin(2\pi\nu_1 t + \phi) \quad (3)$$

where A and ϕ are constants depending on the initial position and velocity. For example, if the mass starts from a position $x = x_0$, with zero velocity, then $A = x_0$ and $\phi = 90^\circ$, and Eq. (3) becomes

$$x = x_0 e^{-\frac{R}{2M}t} \cos 2\pi\nu_1 t \quad (4)$$

Since the solution is the product of a negative exponential function and a sinusoidal function, the amplitude of the displacement will diminish a little bit more with each succeeding cycle of oscillation and eventually the displacement becomes zero again. This is called a damped harmonic oscillation and is physically what we see any time a real spring or pendulum is disturbed and then allowed to oscillate freely. The damping of the oscillations can also be looked upon as representing a conversion of mechanical energy into heat which is proceeding at the instantaneous rate $R(dx/dt)^2$.

We now consider the solution of the inhomogeneous equation [Eq. (1)]. From the theory of linear differential equations, the solution of an inhomogeneous equation can be expressed as the sum of solutions of the homogeneous and inhomogeneous equation. Thus a general solution can be written down in which one term is the

solution [Eq. (3)] while the second is the particular integral satisfying Eq. (1).

$$x = Ae^{-\frac{R}{2M}t} \sin(2\pi\nu_1 t + \phi) + \frac{F_0}{2\pi M} \frac{\cos(2\pi\nu t + \alpha)}{\sqrt{4\pi^2(\nu_0^2 - \nu^2)^2 + \frac{\nu^2 R^2}{M^2}}} \quad (5)$$

where $\nu_0 = (1/2\pi) \sqrt{K/M}$ is the natural frequency for the undamped oscillator and α , the phase angle between the applied force and the displacement, is defined by

$$\tan \alpha = \frac{\nu R}{2\pi M(\nu_0^2 - \nu^2)} \quad (6)$$

Since the first term in Eq. (5) becomes vanishingly small and can be neglected after a period of time has elapsed, it is called the transient part of the solution. The particular integral maintains a constant amplitude as long as the driving frequency does not change, and it is called the steady-state part of the solution.

The steady-state solution for the instantaneous velocity is also of great interest

$$v = \frac{dx}{dt} = \frac{F_0\nu}{M} \frac{\cos(2\pi\nu t + \beta)}{\sqrt{4\pi^2(\nu^2 - \nu_0^2)^2 + \frac{R^2\nu^2}{M^2}}} \quad (7)$$

where β , the phase angle between applied force and velocity, is defined by

$$\tan \beta = \frac{2\pi M(\nu^2 - \nu_0^2)}{\nu R} \quad (8)$$

It is seen that both displacement and velocity have amplitudes which depend on the frequency of the applied force. The form of Eq. (5) and (7) is such that there must exist frequencies for which each achieves a maximum value. The frequencies which produce these maximum values can be found by differentiating the displacement or velocity function with respect to frequency, setting the derivative equal to zero, and solving for ν . In this way, it is deduced that the amplitude of x becomes a maximum when

$$\nu = \sqrt{\nu_0^2 - \frac{R^2}{8\pi^2 M^2}} \quad (9)$$

while the amplitude of v becomes a maximum when

$$\nu = \nu_0 \quad (10)$$

This latter frequency ν_0 which is the natural frequency of the undamped oscillator is customarily referred to as the resonance frequency of the oscillator. The phase difference between the force and velocity at resonance is zero. Thus the velocity will achieve its largest magnitude in the part of the cycle when the push is greatest, confirming what we sense intuitively in pushing a swing. The displacement resonance occurs at a

frequency slightly different from the resonance frequency, but the difference becomes smaller as R decreases. The velocity resonance is of significance in discussing energy because the rates of energy transfer into and out of the oscillator depend on velocity. The external periodic force is doing work on the oscillator at the instantaneous rate of Fv , while the oscillator is working against the damping force at the instantaneous rate of $-Rv^2$. Thus energy is being simultaneously absorbed and dissipated. Since the instantaneous rates vary periodically with time, it is more meaningful to calculate average rates per period and then compare. Such a calculation (see reference 2) shows that the average rate of energy absorption is exactly equal to the average rate of energy dissipation and has the magnitude $(F_0^2/2R) \cos^2 \beta$. At velocity resonance $\cos^2 \beta = 1$, and these rates of absorption and dissipation will have maximum magnitudes of $F_0^2/2R$.

Thus we find that a mechanical oscillator will resonate when a periodic external force with a frequency equal to the natural frequency of the oscillator acts on it. In addition, the rate of absorption of energy from the external source is a maximum at this same resonance frequency. This second property of maximum rate of energy absorption becomes useful in the discussion of resonance phenomena in systems where resonance cannot be described in terms of what happens to the state variables of position and velocity.

There is an exact analogue to this analysis in the electrical circuit consisting of an inductance L , a capacitance C , and a resistance R in series and driven by an alternating emf, $E_0 \cos 2\pi\nu t$. The differential equation for the variation of charge q with time is

$$L \frac{d^2q}{dt^2} + R \frac{dq}{dt} + \frac{q}{C} = E_0 \cos 2\pi\nu t \quad (11)$$

and resonance will occur under the same corresponding conditions as for the mechanical oscillator (see ALTERNATING CURRENTS).

Resonance Phenomena in Atomic-sized Systems.

The exact theory explaining the processes whereby systems composed of atoms absorb and emit energy is based on the principles of quantum theory. Nevertheless, such processes still show some physical analogy to resonance in a mechanical oscillator. A simple example is the single atom consisting of one or more electrons bound to a nucleus by predominantly electrostatic forces. Quantum theory predicts that the atom can exist only in a set of discrete energies in contrast to the continuous range of energies which in principle is available to a large-size satellite system such as the earth and moon. If the atom changes from a higher-energy state E_i to a lower-energy state E_f , energy in the form of electromagnetic radiation is given off and the frequency of the radiation ν_{if} is related to the energy difference between the two states by the equation:

$$\nu_{if} = \frac{E_i - E_f}{h} \quad (12)$$

h is the well-known Planck constant of action and has a value of 6.625×10^{-27} erg sec. This frequency and others which connect discrete energy states consistent with the so-called selection rules for the atom can be pictured as a set of frequencies characteristic of the particular atom. By analogy with resonance in a mechanical oscillator absorption of energy at a maximum rate might be expected to occur when there is radiation incident on the atom with a frequency which matches one of these frequencies. In quantum mechanics, the meaningful index for such a process taking place is the probability that an energy transition will occur a time t after being exposed to the radiation. When calculated, this probability is found to be proportional to

$$\frac{1 - \cos 2\pi(\nu_{ij} - \nu)t}{(\nu_{ij} - \nu)^2} \quad (13)$$

(see references 3 and 4).

Even though this probability function is not of the same mathematical form as the expression for rate of energy absorption derived in the section on "Resonance in a Simple Mechanical Oscillator," because of its dependence on $(\nu_{ij} - \nu)^2$ instead of $(\nu_0^2 - \nu^2)$, it can be looked upon as establishing a condition for a resonance type process. It predicts that the likelihood of resonance absorption becomes very large when the external frequency approaches something resembling a natural frequency of the atom. A distinctive example of this kind of resonance absorption is the phenomenon in the solar spectrum described in the introduction. The radiation from the hot core of solar gases is characterized by a continuous spectrum. In passing through the cooler gases of the sun's outer atmosphere, radiation will be absorbed at those frequencies which match frequencies of atomic transitions in the cool gas. These blocked out lines in the continuous spectrum show up as dark lines against the background. They are called Fraunhofer lines. The rare gas helium was first discovered as a consequence of these observations.

Another important class of atomic resonance phenomena and one in which there is great current interest concerns the behavior of nuclei and electrons in magnetic fields (see MAGNETIC RESONANCE and references 5, 6 and 7). If we start by using a classical analogy, the nucleus and electron can be thought of as being like little spinning magnetized tops with the axis connecting magnetic poles lying along the axis of spin. Being like a spinning top means the particle possesses the mechanical property of angular momentum. Being magnetized, the top will be subject to a torque if a magnetic field is applied along a direction different from that of the magnetic axis. Since the particle has angular momentum, the torque will cause the spin axis to precess about the direction of the applied magnetic field with a characteristic frequency called the Larmor frequency. This is similar to the precession of a spinning top due to the earth's gravity. The Larmor frequency is equal to $g\mu_0 H/h$, where H is

the applied field and h is Planck's constant. μ_0 is a nuclear magneton if the particle is a nucleus and a Bohr magneton if it is an electron. A magneton is the unit in which the particle's magnetic moment is measured. A nuclear magneton has a value of 5.050×10^{-24} erg/gauss. A Bohr magneton has a value of 0.927×10^{-20} erg/gauss. g is the Lande-factor, a special number in atomic and nuclear physics which appears in the ratio of the magnetic moment of a particle to its angular momentum. It is 2.00 for a free electron and 5.58 for a proton. If a radio-frequency (rf) magnetic field is applied in a plane perpendicular to H with a frequency exactly equal to the Larmor frequency, the particle will be subjected to an additional steady torque tending to change its angle with H . But here the quantum nature of the particle must affect the physical interpretation of what happens. The component of the angular momentum, and hence of the magnetic moment, along H can assume only certain discrete values. This means that the energies corresponding to these orientations can have only discrete values differing in an amount which turns out to be $g\mu_0 H$. If the frequency of the rf magnetic field is exactly $g\mu_0 H/h$, it can be demonstrated by a transition probability argument that transitions to either a higher or a lower magnetic energy state become very likely. If this is a system of particles in thermal equilibrium satisfying Boltzmann statistics, there will be more atoms in lower than higher states, and thus there will be a net absorption of energy from the rf field. This is called nuclear magnetic resonance (NMR) when changes in nuclear magnetic states are induced and electron paramagnetic resonance (EPR) when changes in electronic magnetic states are induced. The NMR frequency for a proton in water is $4.258H$ kc where H is in gauss, and the EPR frequency for a free electron is $2.80H$ Mc. The applications of magnetic resonance techniques to the studies of solids have proven very fruitful during the last decade. A very well-defined electron spin resonance can be observed if a sample of diphenylpicryl-hydrazyl (DPPH) is placed in a 3-cm waveguide and a transverse magnetic field of 3570 gauss applied. The resonance appears as a distinct reduction in the amount of microwave power transmitted past the region where the sample is located.

RHEOLOGY

When a force f is applied to a body, four things may happen. The body may be accelerated, strained, made to flow, and slid along another body. If these four responses are added to each other, one can write for motion in one direction

$$f = m\ddot{x} + r\dot{x} + sx + f_0 \quad (1)$$

where m is the mass, r is a damping parameter related to viscosity, s to elasticity, and f_0 to the yield value. Evaluation of the coefficients, m , r , and s involves the measurement of displacements, x , and their time derivatives in a manner which links these kinematic variables via an equation of state such as Eq. (1) to stress, σ (force per unit area), and its time derivatives.

Scope of Rheology. In contrast to the discipline of mechanics wherein the responses of bodies to unbalanced forces are of concern, rheology concerns balanced forces which do not change the center of gravity of the body. Rheology is the science of deformation and flow, and therefore is concerned primarily with the valuation of the coefficients r and s of Eq. (1). The coefficients account for most of the energy dissipated and stored, respectively, during the process of distorting a body.

Most rheological systems lie between the two extremes of ideality: the Hookean solid and the Newtonian liquid.

Measurements of Viscosity and Elasticity in Shear. Simple Shear. Shear viscosity η and shear elasticity G are determined by evaluating the coefficients of the variables \dot{x} and x , respectively, which result when the geometry of the system has been taken into account. The resulting equation of state balances stress against shear rate $\dot{\gamma}$ (reciprocal seconds) and shear strain γ (dimensionless) as the kinematic variables. For a purely elastic, or Hookean, response,

$$\sigma = G\gamma \quad (2)$$

and for a purely viscous, or Newtonian, response

$$\sigma = \eta\dot{\gamma} \quad (3)$$

As a consequence, G can be measured from stress-strain measurements, and η from stress-shear rate measurements.

Elasticoviscous behavior is described in terms of the additivity of shear rates:

$$\dot{\gamma} = \frac{\sigma}{\eta} + \frac{\dot{\sigma}}{G} \quad (4)$$

whereas viscoelastic behavior is characterized by the additivity of stress according to Eq. (1):

$$\sigma = G\gamma + \eta\dot{\gamma} \quad (5)$$

See reference 1 for further information on rheological bodies.

Relaxation. Numerous attempts have been made to fit simplified mechanical models to the two behavior patterns described by Eqs. (4) and (5). One can picture the elastic element as a spring arrayed in a network parallel with the viscous element to give essentially a (Kelvin) solid with retarded elastic behavior, wherein

$$\frac{\eta_k}{G_k} = \lambda \text{ sec (retardation time)} \quad (7)$$

or as a series (Maxwell) network which flows when stressed or relaxes under constant strain:

$$\frac{\eta_m}{G_m} = \tau \text{ sec (relaxation time)} \quad (8)$$

and transient experiments may be designed to measure these parameters singly. In real systems, a single relaxation (or retardation) time fails to account for experimental results. A distribution of relaxation times exists (see RELAXATION).

Dynamic Studies. When Eq. (1) is written in the form

$$\ddot{x} + 2k\dot{x} + \omega_1^2 x = 0 \quad (1b)$$

the equation suggests that the variation in stress be cyclic. Rheometers are designed so that the system may oscillate in free vibration of natural resonant frequency ω_1 , or else so that a cyclic shearing stress of the form $f_0 \cos \omega t$ is impressed on the sample over a frequency range which spans ω_1 . In neither case is the material strained beyond its range of linearity. Equation (1b) represents a damped harmonic oscillator, providing that the coefficients are constant (i.e., providing that they do not depend on the strain magnitude). Not all systems meet this requirement in the strict sense, with the result that one of the first consistency checks which the experimenter makes is for linearity. Doubling the amplitude of oscillation should double the stress and should not change the phase relationships between the cyclic stress and the deformation.

See RESONANCE and see reference 2 for more information on dynamic studies.

Time-temperature Equivalence. Steady-state Phenomena. The creep of a viscoelastic body or the stress relaxation of an elasticoviscous one are employed in the evaluation of η and G . In such studies, the long-time behavior of a material at low temperatures resembles the short-time response at high temperatures. A means of superposing data over a wide range of temperatures has resulted which permits the mechanical behavior of viscoelastic materials to be expressed as a master curve over a reduced time scale as large as twenty decades, or powers of ten (see references 3 through 5).

Polymeric materials generally display large G values (10^{10} dynes/cm² or greater) at low temperatures or at short times of measurement. As either of these variables is increased, the modulus drops, slowly at first, then attaining a steady rate of roughly one decade drop per decade increase in time. If the material possesses a yield value, this steady drop is arrested at a level of G which ranges from 10^7 downward.

Dynamic Behavior. The application of sinusoidal stress to a body leads inevitably to the complex modulus G^* , where

$$G^* = G' + iG'' = G' + i\omega\eta' \quad (9)$$

where G' is the in-phase modulus (σ/γ) which represents the stored energy, and G'' is the out-of-phase modulus ($\sigma/\dot{\gamma}$) representing dissipated energy (as its relation to η' suggests); the variable against which G' and η' are determined is the circular frequency ω . Superposition of variable temperature data or variable frequency data provides a master curve of the type described for the steady-state parameters.

Problems in Three Dimensions. State of Stress. The forces and stresses applied to a body may be resolved into three vectors, one normal to an arbitrarily selected element of area and two tangential. For the xy plane the stress vectors are σ_{xx} , and σ_{xy} , σ_{yx} , respectively. Six analogous stresses exist for the other orthogonal orientations, giving a total of nine quantities, of which three exist as commutative pairs ($\sigma_{xy} = \sigma_{yx}$). The state of stress, therefore, is defined by three tensile or normal components (σ_{xx} , σ_{yy} , σ_{zz}) and three shear or tangential components (σ_{xy} , σ_{yz} , σ_{zx}). The shear components are most readily applicable to the determination of η and G .

Strain Components. For each stress component σ there exists a corresponding strain component γ . Even for an ideally elastic body, however, a pure tension does not produce a pure γ_{xx} strain; γ components exist which constrict the body in the y and z directions.

The complete stress-strain relation requires the six σ 's to be written in terms of the six γ components. The result is a 6×6 matrix with 36 coefficients, k_{rs} , in place of the single constant. Twenty-one of these coefficients (the diagonal elements and half of the cross elements) are needed to express the deformation of a completely anisotropic material. Only three are necessary for a cubic crystal, and two for an amorphous isotropic body. These parameters are discussed in reference 6.

Similar considerations prevail for viscous flow, in which the kinematic variable is $\dot{\gamma}$.

ROTATION—CIRCULAR MOTION

Circular or rotary motion is very common and is best exemplified by a wheel rotating on an axle or a particle revolving in a circle about an attracting center. The case of a fixed axis will be considered in this section. This and related topics are elaborated on in greater detail in most college physics texts; in particular, "University Physics" by F. W. Sears and M. W. Zemansky is recommended.

Consider, as in Fig. 1, a line fixed in the plane of the wheel or orbit and terminating at the axis of rotation. A second radial line is fixed in the body and also terminating on the axis. The angle between these two lines specifies the position or orientation of the orbiting particle P or a section of the rotating wheel. Certain equations are more simply written if this angle is expressed in radians, but revolutions or degrees are sometimes used.

If θ changes from θ_1 to θ_2 as time increases from t_1 to t_2 , then the average angular velocity is defined as

$$\omega_{ave} = \frac{\theta_2 - \theta_1}{t_2 - t_1} = \frac{\Delta\theta}{\Delta t}$$

The instantaneous angular velocity, ω , is the value which this ratio approaches as $\Delta\theta$ and Δt become small. It is most advantageously expressed in radians per second.

Again, if ω is not constant but changes from ω_1 to ω_2 as t increases from t_1 to t_2 , then the

FIG. 1. Body rotating about a fixed axis through O.

average angular acceleration is

$$\alpha_{\text{ave}} = \frac{\omega_2 - \omega_1}{t_2 - t_1} = \frac{\Delta\omega}{\Delta t}.$$

The instantaneous acceleration, α , is the limit which this ratio approaches as $\Delta\omega$ and Δt become small; α is most advantageously expressed in radians per second per second.

In calculus notation $\omega = d\theta/dt$ and $\alpha = d\omega/dt$. Inversely,

$$\theta = \int \omega dt$$

and if ω is known as a function of t , then the integration may be effected.

Also

$$\omega = \int \alpha dt$$

and may again be evaluated. A simple situation is a constant α , and this case is discussed fully in the reference cited.

Next, consider a particle in a circular orbit of radius r , or a particle in the plane of a wheel a distance r from the center but not necessarily on the rim. Such a particle moves along a circular arc of length $s = r\theta$, where θ must be in radians; s and r are both linear quantities and have the same units of length: feet, meters, etc. Here linear implies a length, not necessarily along a straight line, and is contrasted with an angular quantity which implies an angle of some sort. The equation $s = r\theta$ is the connection between linear and angular quantities and is the basis for a useful analogy between motion along a straight line and rotation about a fixed axis.

For this same particle moving in a circular arc, if s and θ change by Δs and $\Delta\theta$ and in the time Δt , then

$$\frac{\Delta s}{\Delta t} = r \frac{\Delta\theta}{\Delta t} \text{ or } v = r\omega.$$

By the same reasoning, $a = \alpha r$. Of course v is the instantaneous velocity along the arc (tangential to the arc) and a is the instantaneous tangential acceleration.

There is another component of acceleration involved in this circular motion. The linear velocity v is a vector quantity. Whenever v changes, in either magnitude or direction, there is an acceleration. The acceleration of the preceding paragraph, $a = \alpha r$, arises because the particle is changing the magnitude of its tangential velocity, that is the particle is either speeding up or slowing down. But of course v , being along the tangent, is always changing in direction, and this amounts to an acceleration too. Derivations of this acceleration can be found in various texts and it turns out to be $a = v^2/r = \omega^2 r$. This acceleration is directed inward along the radius (it is thus at right angles to the tangential acceleration) and is sometimes called radial acceleration or centripetal acceleration. (A more advanced treatment of orbital motion would employ the polar coordinates (r, θ) . Then if the particle moves along the radius, there would be still another acceleration along the

radius, and the total radial acceleration in this notation is

$$\frac{d^2 r}{dt^2} = \omega^2 r$$

The concept of kinetic energy is first developed in translational motion and is defined as $\frac{1}{2}mv^2$ where m is the mass of some particle moving with the velocity v . Kinetic energy is a scalar quantity and if there are two particles, their kinetic energies just add. Applying this to rotation, a rigid body rotating about a fixed axis, may be broken into small particles of mass m_1, m_2, \dots having velocities v_1, v_2, \dots respectively. The total kinetic energy is then

$$\frac{1}{2}m_1v_1^2 + \frac{1}{2}m_2v_2^2 \dots$$

But $v_1 = \omega r_1$, $v_2 = \omega r_2$ where the ω is the same for all particles. So the kinetic energy equals

$$\frac{1}{2}m_1\omega^2r_1^2 + \frac{1}{2}m_2\omega^2r_2^2 \dots = \frac{1}{2}(\omega^2)(m_1r_1^2 + m_2r_2^2 + \dots)\omega^2.$$

The quantity in the parentheses, usually denoted by I , is called the moment of inertia of the rotating body, and it plays the role for rotation that m , the inertia, plays for translation. Thus kinetic energy $= \frac{1}{2}I\omega^2$ in analogy to kinetic energy $= \frac{1}{2}mv^2$. The moments of inertia of various bodies are listed in tables.

Extending this analogy, linear momentum is defined as mv . This suggests that angular or rotational momentum could be defined as $I\omega$. This is a satisfactory definition of angular momentum for a rigid body, but a more general definition of angular momentum is $mvr \sin \theta$ where θ is the angle between v and r . Angular momentum is a very fundamental quantity because it remains constant for an isolated system. Also it is found to consist of integral multiples of a certain smallest amount of angular momentum. That is, angular momentum can be added to a body or taken from a body only in integral multiples of this smallest constant quantity. A photon for instance is found to possess a quantum of angular momentum. This property of angular momentum is particularly important for small bodies such as rotating molecules.

Now these accelerations, which in turn imply changes in rotational kinetic energy and angular momentum, are brought about by the application of forces. Let us consider the two cases for the two components of the accelerations, the radial and the tangential components. We of course will use Newton's law $F = ma$ where F is the resultant force applied to m , a is the acceleration of m , and a is in the direction of F . Thus a radial acceleration is associated with a radial force and a tangential acceleration with a tangential force.

Case I. Force in the Radial Direction. Since there is no tangential force, the tangential acceleration is zero and the particle (or wheel) moves with constant angular velocity and constant tangential velocity. Further, for strictly circular motion, the acceleration is just $\omega^2 r$ directed toward the center and from Newton's second law, $F = m\omega^2 r$ also directed toward the

center. This force is called the centripetal force and is the radial force which must be applied to a mass m in order to keep it moving in a circular path. If this force were not applied, the particle would not move in the circular path, but it would move along a straight line in accordance with Newton's first law.

There are many examples of this centripetal force. If a mass tied to a string is whirled in a circle, then this force must be applied to the mass by the string. If a car is rounding a curve, then the highway must exert on the car a force which is toward the center of the path. In either example, if the force is not exerted (that is, there is no force on the mass) the particle would move along a straight line rather than in a circle.

Case II. Force in the Tangential Direction. A particle speeding up or slowing down in its circular path has a tangential acceleration, a , which is related to its angular acceleration by $a = r\alpha$. Again by Newton's second law this requires a tangential force $F = ma = mr\alpha$. This can be extended to the case of many particles, as in a rotating wheel, by the following maneuvers. Multiply both sides by r obtaining $rF = mr^2\alpha$. The left hand side is recognized as the torque about the axis of rotation of the force F . Of course there is one such equation for each of the many particles in the wheel. Adding all such equations one gets on the left hand side just the total torque, usually denoted by L . On the right hand side, since α is the same for all particles, the summation will introduce a combination we have seen before and the sum is just $I\alpha$. So $L = I\alpha$ which is the rotational analog of $F = ma$. Thus torque, L , is the analog of F and, as before, I is the analog of m .

Centrifugal force is referred to in many text books and Coriolis force, while much less common, is sometimes mentioned. In contrast, some texts scrupulously avoid these two forces or show a greater distaste for centrifugal force than CORIOLIS FORCE. An attempt will be made to reconcile these points of view. A key idea is the fact that different observers watching the same chain of events may record quite different observations and hence give quite different explanations. An inertial observer, that is, one at rest with respect to the fixed stars, and a rotating observer may do just that. Their explanations are equally valid, at least, the General Theory of Relativity admits both inertial and non-inertial observers on equal terms.

Consider first a ball tied to a string and whirled in a horizontal circle and then released. Any bystander is essentially an inertial observer and would see the ball fly off along the tangent in a straight line. Consider next the apparatus shown in Fig. 2. It consists of a horizontal turntable, T , on which there is a steel ball, B , and an electromagnet, M . The ball rolls on a toy "magic slate," S , on which it leaves a trace of its path. The slate plays the role of a rotating observer and the trace left on it is a record of how it observes the motion. The procedure is to energize the magnet with the ball in contact with it, set the table into rotation

FIG. 2. Reprinted from *American Journal of Physics*, 27, (6), 429 (September, 1959).

and then release the ball. The dashed line represents the path followed. Notice that on the slate the ball starts rolling in a radial direction and then curves. The inertial observer sees a tangential motion of a released ball, while the rotating observer sees a radial motion.

Before the ball is released, the inertial observer says there is just one force acting on the ball, the tension in the string. This force on the ball is directed toward the center of the circle and is called centripetal force. The inertial observer also sees the ball accelerating toward the center and says that the centripetal force produces the centripetal acceleration. When the ball is released the centripetal force disappears, there is no force on the ball and the ball then travels in a straight line at constant speed.

In contrast, the rotating observer says that before the ball is released it is at rest. It has no motion and no acceleration with respect to the slate and is therefore in equilibrium. Hence two equal but opposite forces act on the ball. These two forces are a centripetal force applied by the magnet and a centrifugal force which acts radially outward. When the ball is released, the centripetal force ceases. This allows the centrifugal force, which continues to act, to accelerate the ball radially outward. Then follows a curvature of the path caused, according to the rotating observer, by the Coriolis force. This force appears when the ball acquires a velocity, v , with respect to the rotating observer and turns out to be always perpendicular to v . It is only the rotating observer who uses the concepts of centrifugal and Coriolis force. Notice also that while centrifugal and centripetal force are equal and opposite, they are not the action and reaction of Newton's Third Law as is implied in some texts. Actually since they act on the same body, they are equilibrants one of the other.

S

SCHRÖDINGER EQUATION

The Schrödinger equation, first obtained in 1926¹, was an extension of de Broglie's hypothesis, proposed two years earlier,² that each material particle has associated with it a wavelength λ related to the linear momentum p of the particle by the equation

$$\lambda = \frac{h}{p} \quad (1)$$

where h is Planck's constant. Since any sinusoidally varying wave motion of amplitude ψ and wavelength λ satisfies the differential equation*

$$\nabla^2\psi + \frac{4\pi^2}{\lambda^2}\psi = 0 \quad (2)$$

matter waves would obey the equation

$$\nabla^2\psi + \frac{4\pi^2}{h^2}p^2\psi = 0 \quad (3)$$

In particular, a particle of mass m with no forces acting on it has energy $E = \frac{1}{2}mv^2 = p^2/2m$, or $p^2 = 2mE$. Equation (3) may thus be written

$$\nabla^2\psi + \frac{8\pi^2m}{h^2}E\psi = 0 \quad (4)$$

This is the Schrödinger equation for a free particle. Of greater importance is the equation for a bound particle for which the binding force can be related to a potential energy V . In this case, the total energy of the particle is equal to the sum of the kinetic and potential energies, i.e., $E = p^2/2m + V$, or $p^2 = 2m(E - V)$. Equation (3) thus becomes

$$\nabla^2\psi + \frac{8\pi^2m}{h^2}(E - V)\psi = 0 \quad (5)$$

This is known as the time-independent Schrödinger equation. Its great utility lies in the fact that it enables one to calculate energy levels, or eigenvalues, of the energy E (see QUANTUM THEORY). The remarkable agreement of the results of the equation with experimental fact has led to its being regarded as one of the fundamental equations of physics.

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$$

The more advanced formulation of the Schrödinger equation is based on the operator concept of quantum theory together with the Hamiltonian methods of classical mechanics. Specifically, to each dynamical variable q_i , there is a conjugate momentum p_i . The fundamental postulate of quantum mechanics states that for each pair (q_i, p_i) , the equation

$$p_i\psi = -i\hbar \frac{\partial\psi}{\partial q_i} \quad (6)$$

holds, where $\hbar = h/2\pi$. That is, $i\hbar\partial/\partial q_i$ is an operator, which, when applied to the wave function ψ , is equivalent to multiplying by p_i . In the Hamiltonian function $H(p_i, q_i)$, each p_i is replaced by its corresponding operator. The result is the Hamiltonian operator $H(-i\hbar\partial/\partial q_i, q_i)$, which, when it operates on the wave function, is equivalent to multiplying by the energy E , viz.,

$$H(-i\hbar\partial/\partial q_i, q_i)\psi = E\psi \quad (7)$$

This is the generalized form of the time-independent Schrödinger equation. It reduces to Eq. (5) when applied to a single particle, but it has the advantage that the application to systems of many particles can be carried out in a straightforward manner.

The time-dependent form of the Schrödinger equation is obtained by replacing E by its operator $E \rightarrow i\hbar\partial/\partial t$, so that

$$H\left(-i\hbar \frac{\partial}{\partial q_i}, q_i\right)\psi = i\hbar \frac{\partial}{\partial t}\psi \quad (8)$$

For applications of the various forms of the Schrödinger equation, the reader should consult the article on WAVE MECHANICS and references therein.

SECONDARY EMISSION

In its most general sense, secondary electron emission refers to the ejection of electrons from matter under the impact of rapidly moving particles such as electrons, ions, or neutral atoms. When the atoms of the material bombarded are in the gaseous state, the phenomenon is more commonly referred to as impact ionization. In practice, the term is mainly used in connection with the emission of electrons from solids under electron bombardment as in photomultipliers, and for the ejection of electrons at the cathode of gas discharge devices under the action of positive ions.

Historical Background. Secondary emission from solids was first observed with electrons as incident particles. The effect was discovered by Austin and Starke in 1902 in the course of studies on the reflection of fast electrons from metals. Upon increasing the angle of incidence of the primary electrons away from the normal, Austin and Starke observed that the current into the target first decreased to zero and then actually reversed. They concluded that not only are the incident electrons reflected but other electrons are also ejected from the plate such that the total number leaving exceeds the number arriving. The effect was found to be strictly proportional to the number of primary electrons. Furthermore, it was found to be more pronounced for metals of high density, and it was observed to increase rapidly with the angle of incidence. Shortly thereafter, P. Lenard (1903) showed that the secondaries are emitted diffusely, that they possess low energies of the order of a few volts independent of primary energy or target material, that the yield goes through a maximum at a few hundred volts, and that the process occurs in insulators as well as metals. Lenard concluded that the formation process is fundamentally an atomic one and therefore largely independent of the state of aggregation. This deduction has been confirmed in recent years.

The emission of secondary electrons from solids under ion bombardment was first demonstrated in 1905 by J. J. Thomson and established to be very similar to the case of electron bombardment by C. Füchtbauer (1906). The secondaries were again found to have energies of a few volts, essentially independent of the nature of the bombarding ion, its velocity, or the properties of the solid bombarded. Shortly thereafter, N. R. Campbell (1911) established the same characteristics for the electrons emitted under α -particle bombardment, the so-called δ -rays.

Secondary Emission Under Electron Bombardment. The basic features of the phenomenon as clarified by subsequent investigations may be summarized as follows. For all pure metals and elemental semiconductors free from surface oxides or gas contamination, the total yield δ , defined as the total number of electrons emitted per incident primary electron, never exceeds a value of about 2. Out of this total, the number of backscattered electrons per incident primary η

may be as high as 0.5 for high atomic number elements and energies in excess of a few kilovolts. The distinction between the two kinds of emitted electrons is based on their energy distribution. The true secondaries are characterized by their low energies, peaked at about 2 eV for all metals, and a Maxwellian-like energy distribution with a mean value close to 5 eV independent of primary energy. The backscattered electrons above about 50 eV emerge with energies all the way to the primary energy, but only a few per cent are truly elastically reflected, having lost no appreciable energy in the solid (as indicated in Fig. 1).

The backscattered fraction η is almost constant with changing primary energy for low atomic number elements ($Z \lesssim 30$), varying nearly linearly with Z from 0.04 for Be ($Z = 4$) to 0.28 for Ni ($Z = 28$). For heavier elements, η increases slowly with primary energy from values less than for Ni to limiting values as high as 0.45 for Pt ($Z = 78$) above 5 kV. The yield of low energy secondaries $\Delta = \delta - \eta$ starts from zero at a finite voltage in the neighborhood of 10 to 15 eV and rises to a maximum value in the range of 0.5 to 1.5 between 100 and 700 volts for all metals. Thereafter, it decreases steadily until at energies above a few kilovolts, Δ becomes less than the backscattered fraction η .

In sharp contrast to thermionic or photoelectric emission, neither the onset of emission nor the maximum yield is directly related to the work function of the metal. Instead, it has been found that the maximum yield Δ_m increases steadily within each period of the atomic table as successive elements are added; the alkali metals have the lowest yield in each case as illustrated for the fourth period by Fig. 2.

The presence of surface impurities or oxides can increase the yield considerably, primarily owing to the fact that secondaries can travel larger distances in insulators than in metals, where they lose energy rapidly to the conduction electrons. Measurement of the yield for insulators, such as BaO, MgF₂, MgO, and KCl, have shown that yields of 6 to 10 or higher can be obtained for such materials depending on the method of preparation, the yields remaining well above unity even at primary energies of many kilovolts. It is for this reason that in technical applications in which it is desired to obtain the largest possible yields, one utilizes alloys which upon heat treatment form an oxide layer containing BeO or MgO on their surfaces. The most common of them are alloys of Cu-Be and Ag-Mg.

In addition to the larger mean free path for secondaries, such complex insulating surfaces often show an additional enhancement of their yield owing to internal electric fields, which act to increase the fraction of electrons able to escape, thus resulting in yields often many times those normally attainable. The presence of charging effects is characterized by a strong increase in the relative number of very low-energy secondaries. It is generally accompanied by a time delay in the emission process, which is long compared

FIG. 1. Typical energy distribution of the electrons emitted from metals under electron bombardment by 300-v primaries; δ is the total yield, Δ the yield of true secondaries, and η the backscattered fraction.

FIG. 2. Typical secondary-electron yield curves for metals. Data shown for elements in the 4th period of the atomic table.

with that for normal secondary emission, which is completed in less than 10^{-12} second.

Secondary Emission Under Ion Bombardment. As already noted, secondary emission under ion bombardment resembles closely the phenomenon under electron bombardment, especially for very high ion energies, when the velocities of the incident ions exceed the orbital velocities of electrons in the atoms of the solid. The principal difference is the somewhat larger yield for ions, brought about by their greater rate of energy loss and therefore ionization near the surface. For protons, the maximum yield is close to 4 occurring at an incident energy of about 100 kV. For α -particles or helium ions, the maximum yield is almost four times as large since the rate of ionization is proportional to the square of the effective charge. Another important difference in the case of fast ions is that all clean metals show closely the same yield at a given energy, because of a proportionality between the probability of secondary formation and absorption in all metals. Again, the presence of oxide layers can greatly enhance the attainable yield. For ions of very low velocity, the phenomenon becomes more complex since the relative values of the ionization potential and the work function of the solid begin to play a dominant role. The electron-emission process is then determined primarily by the energy made available when an electron from the metal drops into the ionized outer level of the approaching ion, rather than by its kinetic energy and state of charge.

Theory. In contrast to thermionic, photoelectric, and field emission, secondary emission under the impact of high-speed particles is an energetic process for which the usual free-electron model of a metal becomes inadequate. Furthermore, in the case of electrons falling on a solid, the strong inelastic scattering by the large number of more firmly bound electrons is the principal factor determining the depth at which the secondaries are formed. The theoretical description therefore consists of finding an expression for the ionization density as a function of depth, and then calculating the probability that the secondaries formed will reach the surface. When the primary particle velocity is high, the theory of Bohr and Bethe for the stopping of charged particles in gases may be used to calculate the scattering and ionization of the incident particles. In the special case of high-energy ions, scattering is negligible and a simple theory was formulated by E. J. Sternglass (1957) that explains the maximum in the yield as reflecting the maximum in the ionization probability for the atoms of the solid.

For the case of low-energy electrons incident on the surface, it is possible to arrive at an approximate expression for the mean depth at which the electrons have been completely scattered and where most of the secondaries are formed. In view of the known rapid exponential absorption of the secondaries in metals, with a mean-free path of only a few atomic layers and an energy expenditure per secondary formed similar to that for gases (~ 30 eV), good agreement with the

observed yields was obtained by E. J. Sternglass (1951). The shape of the yield curve is found to reflect the opposing effects of an increase in the number of secondaries formed and the decrease in their chance of reaching the surface as the primary energy is increased. In insulators, the escape probability is greater, thus leading to larger yields at high primary energies.

For the case of low-velocity rare-gas ions incident, the band-model of a metal can be used to calculate the energy available for the ejection of a conduction electron when a metallic electron neutralizes the incoming ion. The observed yield and energy distribution of the secondaries can then be accounted for rather well as shown by H. D. Hagstrum (1954). At the present time, the principal theoretical problem remaining is to establish the precise role of the surface potential barrier in determining the fraction of the secondaries able to escape.

Applications. The principal application of secondary emission in the field of electronics has been in the amplification of weak electrical currents first suggested by J. Slepian in 1917. The most common use is in the intensification of photoelectrons by successive steps of multiplication in photomultiplier tubes, over-all gains of 10^7 being readily achieved at a very small loss in signal-to-noise ratio. The phenomenon also plays an important role in many types of television camera tubes such as the iconoscope and the image orthicon, and more recently in image-intensifying tubes based on secondary emission from a series of thin foils. Other important applications exist in storage tubes, magnetrons, and high-gain multiplier receiving tubes. Secondary emission under ion bombardment is a fundamental process involved in most gas-discharge devices, and it is also believed to play an important role in high-voltage breakdown phenomena.

SEISMOLOGY

Seismology, the study of earthquakes and attendant phenomena, provides the bulk of man's detailed knowledge of the earth's interior, largely as a result of investigations of the complex seismic waves which propagate throughout the earth following an earthquake. Analyses are based principally on ray theory for elastic body waves of the dilatational and shear types, and on wave theory for traveling elastic surface waves and their standing wave counterparts, the free oscillations of the earth. Seismological studies have, among other things, defined the configuration and structure of the earth's nonrigid outer core, the probably rigid inner core, the rigid mantle with its low-velocity layer at a depth of a few hundred kilometers, and the deeper regions of the earth's crust. In practice, the science includes widely diverse activities ranging from operation of unusual seismographs in the most remote locations of the earth to application of highly sophisticated mathematical techniques to problems involving complex earth models.

Excluding certain near-surface regions, the velocities of dilatational seismic waves range from about 5 km/sec in parts of the crust to a maximum of $13\frac{1}{2}$ km/sec at the base of the mantle; corresponding shear wave velocities range from 3 to 8 km/sec. The shortest periods of interest in the study of waves from distant earthquakes are of the order of $\frac{1}{3}$ second (frequency = 3 cps); the longest periods are about 53 minutes (frequency ≈ 1 cycle/hour), and they correspond to a free oscillation of the earth in the fundamental spheroidal mode.

Free oscillations of measurable amplitudes are generated only by the largest earthquakes. Body and surface waves from large nuclear explosions and many earthquakes may be detected throughout the world; seismic waves from chemical explosions are adequate for exploration to depths of about 50 km or less. Seismic techniques are used extensively in petroleum exploration and for various other geologic purposes.

The largest earthquakes probably release between 10^{24} and 10^{25} ergs in the form of seismic waves, and the few largest shocks account for most of the energy released in this form. Mean annual release is estimated at 9×10^{24} ergs.

Earthquake size as determined by instruments is measured on a logarithmic scale called the Richter *magnitude* scale. In one variation of this scale, the very largest shocks have magnitudes slightly greater than $8\frac{1}{2}$. Energy in ergs is given empirically by $\log E = 11.4 + 1.5M$, where M is the magnitude. A noninstrumental scale for measuring earthquake effects at a given location is called the *intensity* scale; the popular Modified Mercalli version has divisions from I to XII. Whereas an earthquake may produce a range of intensities, it is in principle characterized by a single value of magnitude.

The frequency of occurrence of earthquakes increases by about a factor of 8 or 10 per unit of magnitude as the magnitude decreases. On the

average, only about 25 shocks with a magnitude of 7 or more occur each year, but it has been estimated that there are at least one million earthquakes per year, most of them quite small. About 5000 to 10,000 of these are routinely located and studied.

Most earthquakes occur in certain narrow world-circling belts separated by relatively stable blocks. The circum-Pacific belt is by far the most important, accounting for about 80 per cent of the total activity. Other important features are the trans-Eurasian belt and the mid-ocean belt. The foci, i.e., the points of initiation of the first seismic waves, of most shocks are shallow, i.e., at depths of 60 km or less, but some are as deep as 700 km. Most large shocks are followed by a series of smaller aftershocks which occur in the same general region as the main shock. Aftershocks generally decrease in size and in frequency of occurrence with time but may persist for more than a year following a very large shock. Some earthquakes are preceded by one or a few foreshocks.

The most popular model of the earthquake mechanism is based on the elastic rebound theory which calls for gradual accumulation of elastic strain in a region prior to the release of the strain energy through rupture or by slippage along a preexisting fault. This model explains many features of many earthquakes but is clearly oversimplified and may not be applicable at all to deep shocks. Precise prediction of earthquake occurrence in time and space is not now possible, but current and prospective research offer some promise.

In addition to transient seismic phenomena such as those due to earthquakes and explosions, there is a continuous background noise in the earth which is measurable with modern seismographs over a wide range of periods. For periods of about one second, ground amplitudes at very quiet locations are less than 1 millimicron. Between periods of 4 and 9 seconds, there is a sharp peak in the noise spectrum. The corresponding waves are called storm microseisms and are related, probably through ocean waves, to meteorological disturbances at sea.

Most modern seismographs are of the inertial type, depending upon measurement of the relative displacement between a point fixed to the earth and a mass loosely coupled to the earth. Other instruments measure relative displacement between two points in the earth. There are approximately one thousand seismograph stations in the world. Attempts are currently under way to operate seismographs on the floor of the deep ocean and on the moon.

SEMICONDUCTORS

Semiconductors are materials whose electrical conductivity lies generally between that of metals (10^6 mho/cm) and insulators (10^{-10} to 10^{-20} mho/cm). However, the boundaries are indistinct, and on the one hand the properties of very impure semiconductors are quite similar to those of some metals (semi-metals such as bismuth, for example), and on the other hand, many semiconductors may be strongly insulating if highly purified or measured at low temperature.

As indicated by the above, the properties of semiconductors are extremely variable, and it is partly because of this that they are so interesting and so important both to the physics of the solid state and to electrical technology. The extreme sensitivity to impurities, to temperature, to incident light, to magnetic fields, and to nuclear radiation provides a rich field for the testing of theories of the solid state. Out of the same properties have also arisen such important technical contributions as transistors and integrated circuits, which have revolutionized electronics.

Among the elements, there are at least seven semiconductors. They are boron, silicon, germanium, gray tin, tellurium, selenium, and black phosphorus, while carbon (both diamond and graphite) has some semiconducting properties as do iodine, sulfur, and perhaps others.

There are numerous inorganic and some organic semiconducting compounds. The best known of the inorganics are the compounds of the third and fifth columns of the periodic table, such as gallium arsenide, indium arsenide, indium antimonide, and aluminum antimonide. Also important are the "2-6" compounds, of which cadmium sulfide, zinc sulfide, and zinc oxide are probably the best known. The ionic crystals such as the alkali halides (NaCl) and the alkaline earth oxides, may also be semiconductors under certain conditions. Among the organics, many dyes have electronic conductivity, and such materials as the phthalocyanines may be quite

conducting. Single crystals of members of the quinone family (TCNQ) have been prepared having resistivities as low as 1 ohm cm.

There is no uniformity in the appearance, physical properties, or crystal structure of semiconductors. Some are metallic-looking, while others may be practically transparent. Most are crystalline, but amorphous semiconductors (selenium) and liquid semiconductors (many of the molten sulfides and selenides as well as selenium) are also known. Unlike metals, semiconductors tend to be brittle and hard, rather than ductile. There is no uniformity in the method of preparation. Much of the effort in recent years has been devoted to methods of purification and single-crystal preparation. More than any other group of materials, semiconductors are sensitive to the perfection of the crystal lattice, as well as to the content of foreign impurities. Many semiconductors, especially silicon and germanium, can be drawn in large single crystals from the melt (Czochralski technique). Because of their importance as transistor materials, extensive research has made them probably the purest and most perfect materials available in science.

Other crystals may be grown from the vapor phase, prepared by direct combination, or frozen in tubes in a temperature gradient (Bridgman technique) so as to produce single crystals (see CRYSTALLIZATION).

Basic Theory of Semiconductors. There are several aspects of the theory of semiconductors, and all are needed to understand the electrical properties. The first is the theory of electronic band structure of solids, the second is the theory of electrical transport in solids (we deal here only with *electronic* as distinct from *ionic* conductivity).

The explanation of the temperature and impurity sensitivity of semiconductors in 1930 was one of the first triumphs of the quantum theory of solids, and the history of semiconductor research has been a parallel development of the quantum theory and of experimental research on materials. Even today, however, because of the complexity of the theory and of the calculations, the theory is still incomplete and approximate. One-electron theories still prevail, whereas many-electron theories are needed to treat the problem adequately. As more powerful computers are assigned to the calculations, we shall see rapid extension of theoretical knowledge particularly in terms of details of the properties of various materials.

The "bands" of semiconductor theory are energy bands which are derived from the atomic energy levels of, say, the individual germanium atom, broadened by the interactions between neighboring atoms in the crystal (see ENERGY LEVELS). The upper band, the conduction band, normally empty, corresponds to the first excited state, whereas the lower band, the so-called valence band, usually full of electrons, corresponds to the top normally occupied atomic level. Impurity atoms in the lattice may, at rather low

temperatures, give up an electron to the conduction band, and the semiconductor may then conduct electronically (*n*-type conduction). Other impurities, however, may *take up* electrons from the valence band, which then, rather remarkably, also contributes to conduction, the empty states in the band acting like *positive* charges with the same mass as the electron. Such semiconductors are *p*-type. At sufficiently high temperatures (room temperature for fairly pure germanium, 200°C for silicon), electrons from the valence band may be excited directly across the "forbidden gap" into the conduction band, and both the hole and the electron are conducting. Such semiconductors are *intrinsic* semiconductors, in contrast to impurity (extrinsic) semiconductors.

In the elementary sense, the energy-band picture showing the band gap of the material and the energy location of the levels from which the impurities deliver carriers can be considered a specification of the band structure. For many materials, however, we are now able to specify a more fundamental structure, including the "*E* vs *k*" curves and the "surfaces of constant energy" of the carriers. Only in recent years has this information become available for many materials. The *k* referred to is the coordinate of "*k* or momentum space", where *k* is the reciprocal wavelength of the electron considered as a wave

in the wave-mechanical sense. For a simple semiconductor, dealt with in older books and papers, the *E* vs *k* curve was a parabola, exactly as for an electron in free space, but with a mass different from that of an electron in free space to account for the effects of the lattice. The effective mass, determined by the curvature of the *E* vs *k* curve, may be greater or less than the free-electron mass. The surface of constant energy for a simple semiconductor is a sphere.

As properties of semiconductors became better known, it was realized that the simple model was not adequate. The parabolic *E* vs *k* curve for germanium's conduction band was replaced by a complicated set of curves having minima at *k* = 0 but also at *k* ≠ 0, and the constant energy surfaces, instead of being a single sphere, were sets of four ellipsoids, cigar-like in shape (20 times as long as thick) oriented along the (111) crystal directions (along the diagonals of the basic cube of the lattice). The *E* vs *k* curves for the valence band of Ge are nearly parabolic, but there are three of them. Two of them are centered at *k* = 0 and correspond to two different kinds of holes (light and heavy). They are examples of a *degenerate* valence band.

Once the basic band structure is known, STATISTICAL MECHANICS is available to determine the distribution of electrons over various possible states (conduction band, valence band, and

FIG. 1. Comparison of the older and newer pictures of the band structure of a typical semiconductor.

impurity levels) and to determine the carrier densities p and n . Another important task is to understand the *mobilities* of the carriers, μ_n and μ_p . Much knowledge of this has been gained on many materials during the past few years. The theory of mobilities requires understanding of the various *scattering* processes which hinder the motion of the carriers, the dependence on energy, and the influence of the scattering on the various experimental properties such as conductivity and Hall coefficient. Finally, knowing the carrier densities and mobilities, and one or two other parameters, theories are available to describe other experimental properties such as thermoelectric power, photoconductivity, optical absorption, magnetic susceptibility, and magneto-resistance.

The distribution function which determines the way electrons spread over the various states is the "Fermi" function $1/[1 + \exp(E - E_f/kT)]$, where E_f is the Fermi level, a characteristic marker on the energy-band picture for each sample. Since this function has a simple exponential form $\exp[-(E - E_f/kT)]$ for large E , there results an exponential variation of carrier density with temperature, one of the characteristic properties of semiconductors, the conductivity going to zero at absolute zero. For impurity semiconductors, *saturation* sets in at higher temperatures as the impurity supply of electrons becomes exhausted. The carrier density then remains constant until intrinsic conduction sets in when it again changes exponentially. For germanium, this exponential holds right up to the melting point, 938°C, where the conductivity value is about 1000 mho/cm. Liquid germanium is metallic, some ten times more conducting than the solid.

Determination of the scattering of carriers and calculation of experimental properties in terms of this scattering is equally as important as band structure studies. One must know the various mechanisms of scattering, their dependence on energy and temperature. Scattering of electrons or holes is usually due to (a) lattice scattering, (b) impurity scattering, or (c) scattering by imperfections such as vacancies or dislocations. Each of these has a different magnitude and dependence on energy. Lattice vibrations, or PHONONS, have a characteristic spectrum for each material, and much research in recent years has gone into determination of such spectra. Phonons may be of the *optical* or *acoustic* type (in optical vibrations, adjacent atoms move in opposite phases; in acoustic, the same phase); in some materials, the optical phonons may be the main source determining mobility; in others, the acoustic may be predominant. Many phenomena, such as thermal conductivity, optical absorption, radiative recombination, and tunneling have been used to gain information on phonons.

In some cases, for phenomena such as TUNNELING, phonons may be *required* to observe the phenomenon. Materials which show this effect are called *indirect* semiconductors, since the E vs k curve minima for the conduction band do not lie directly above the valence band maximum, and

hence momentum transfer, provided by phonons, is required for the transition. Germanium, silicon, and silicon carbide are examples of indirect semiconductors, while indium antimonide and gallium arsenide are the best known direct semiconductors. It is only in the latter group that semiconductor laser action is seen, because of the low efficiency of radiative recombination when phonons are required in the process.

Experimental Properties of Germanium. Let us briefly outline the experimental properties of semiconductors using germanium as an example.

Conductivity σ is of course a basic property. It depends upon carrier density and mobility according to the equation $\sigma = ne\mu$, where e is the charge on an electron. Conductivity in the simple theory and for cubic crystals is a scalar (pure number) quantity, but for anisotropic crystals it is a tensor, as are the effective masses, Hall coefficients, and others. The density of carriers is generally determined by use of the Hall coefficient, according to the equation $R = 1/ne$, in electromagnetic units. In modern work, R is given by r/ne , where r is the "Hall coefficient factor" determined by a ratio of two relaxation times for the electron distribution, averaged over the energy surfaces of the particular material. The value of r usually ranges from 0.5 to 2, and in older work was taken to be $3\pi/8$. For p -type semiconductors, the same equations prevail, with p instead of n .

Holes and electrons may coexist in equilibrium only in intrinsic semiconductors, while after light excitation or nuclear bombardment, the electron-hole pairs produced last only for a characteristic time called the *lifetime*. The conductivity for mixed conduction by holes and electrons is:

$$\sigma = e(n\mu_n + p\mu_p)$$

and the Hall coefficient

$$R = \frac{r}{e} \left(\frac{n\mu_n^2 - p\mu_p^2}{(n\mu_n + p\mu_p)^2} \right)$$

Germanium at room temperature has an intrinsic resistivity of 47 ohm cm, the carrier densities being each $2 \cdot 10^{13}/\text{cm}^3$. The electron mobility is $3800 \text{ cm}^2/\text{volt} \cdot \text{sec}^{-1}$; for holes, 1800. These values are much higher than for most metals and many semiconductors, which average 100 to $200 \text{ cm}^2/\text{volt} \cdot \text{sec}^{-1}$. Indium antimonide has the extraordinarily large mobility at room temperature of $70,000 \text{ cm}^2/\text{volt} \cdot \text{sec}^{-1}$. Such high-mobility materials are important for Hall-effect applications.

The sensitivity of germanium and other semiconductors to impurities is enormous. Even at room temperature, arsenic present to the extent of $2 \cdot 10^{12}$ atoms/ cm^3 changes the resistivity by 15 per cent. This is only one part in ten billion! Other donors besides arsenic are phosphorus, antimony, and bismuth, which give up their electrons to the conduction band with only 0.01 eV of energy required (ionization energy). The acceptors boron, aluminum, gallium, and indium take up electrons and have very nearly the same ionization energy.

TABLE 1. ROOM TEMPERATURE PROPERTIES OF SOME SEMICONDUCTORS

Material	Band Gap (eV)	Electron Mobility $\text{cm}^2/\text{volts} \cdot \text{sec}^{-1}$	Hole Mobility $(\text{cm}^2/\text{volts} \cdot \text{sec}^{-1})$	Dielectric Constant, ϵ	Lattice Constant (Å)	Density (g/cm ³)	Melting Point (°C)

By now the effects of over 30 elements in germanium have been studied. Some such as gold may, under certain conditions, either donate an electron or accept as many as three electrons. Such an element is "amphoteric". Some elements such as tin or lead dissolve appreciably, but they seem to have no electrical action.

The boundary between the *p* and *n* regions of a single crystal is of great scientific and technical interest. A single "*p-n* junction" is the heart of the modern silicon or germanium rectifier, while two *p-n* junctions in close proximity (usually less than 10μ) form the basis for the *transistor*. The transition between the donor and acceptor impurities at the boundary requires a potential barrier to keep holes and electrons in place. When voltage is applied in one direction, however, large currents can flow (minority carrier injection), while with voltages in the opposite direction, no current can flow (or a very small one), and the barrier may withstand several thousand volts without breaking down. Transfer of injected carriers from a low-impedance emitter junction to a high-impedance collector junction biased with opposite voltage constitutes transistor action and gives power amplification. Transistors have also been made with gallium arsenide, indium antimonide, and other compounds.

Other Semiconductors. Table 1 gives the basic parameters of a number of semiconductors according to recently published data. For more details the reader should consult the references.

Most known semiconductors fit the general picture described above. There is a large class, however, about which we have only recently begun to get a clear understanding. These are the so-called narrow-band semiconductors, including most organic semiconductors as well as some inorganic ones. These materials may have a very high carrier density, but very low mobility which rises rapidly with temperature. The conductivity mechanism is thought to be a "hopping" mechanism from one atom to the next, rather than

electron wave motion perturbed by scattering centers.

SERVOMECHANISMS

Definition- A servomechanism is a feedback control system in which the difference between a reference input $r(t)$ and some function of a controlled output $c(t)$ is used to supply an actuating signal $e(t)$ to a controller and a controlled system. The actuating signal is amplified in the controller and is used to vary the output of the controlled system in such a manner that the difference between input and output is reduced to zero. A simple block diagram representation of a servomechanism is shown in Fig. 1.

FIG. 1. Block diagram of a servomechanism with unity feedback.

The controlled system may consist of a mechanical structure, a chemical process, a heating system, an electric supply or any system in which a variable can be measured and controlled. The reference input may be a reference level, a sinusoidal or a polynomial function of time, or a discrete, sampled, or programmed set of values. The difference detector is usually matched to the form of the output and input signals. The controller contains signal amplifiers and may also contain power amplifiers which furnish power to an actuating device from an external power source. Actuating devices vary with the controlled system. Actuating devices to position or move mechanical structures may be electromechanical, hydraulic, or pneumatic.

The controller is designed to control a system with known dynamic properties to respond to a specified type of input signal with a specified steady-state and transient performance. The controller may be digital or analog and may be designed for nonlinear or linear operation or may have a linear operating region of actuating signals and a nonlinear saturation zone. Nonlinear systems can be designed with better performance characteristics than linear systems, but linear systems are easier to analyze. A simple linear system with unity feedback will be described.

Linear servomechanisms are analyzed in terms of their transfer function, which can be obtained by taking the Laplace transform of the differential equations of the open loop system with zero initial energy storage. The transfer function is the ratio of the Laplace transform of the output to the Laplace transform of the actuating signal.

$$G(s) = \frac{C(s)}{E(s)}$$

In most cases, $G(s)$ is or can be approximated as a rational algebraic function and can be expressed in the following form.

$$G(s) = \frac{K_n(T_1s + 1)(T_2s + 1) \dots \left[\frac{s^2}{\omega_1^2} + \frac{2\zeta_1}{\omega_1}s + 1 \right]}{s^n(T_as + 1)(T_bs + 1) \dots \left[\frac{s^2}{\omega_a^2} + \frac{2\zeta_a}{\omega_a}s + 1 \right] \left[\frac{s^2}{\omega_b^2} + \frac{2\zeta_b}{\omega_b}s + 1 \right] \dots}$$

The value of the exponent n is used to classify the type of servomechanism. For $n = 0$ (a type 0 servomechanism), the system is often called a regulator or governor, rather than a servomechanism, the distinction being that a servomechanism must contain integration in its transfer function ($n \geq 1$) in order to be able to reduce its steady-state error for a position input to zero.

The control ratio is the closed-loop counterpart of the transfer function.

$$\frac{C(s)}{R(s)} = \frac{G(s)}{1 + G(s)}$$

The ratio of error (or actuating signal) transform to the input signal transform is given by

$$\frac{E(s)}{R(s)} = \frac{1}{1 + G(s)}$$

The characteristic equation for the closed loop system is given by

$$1 + G(s) = 0$$

FIG. 2. Transient response of a Type I servomechanism to a step input.

FIG. 3. Response of Type I servomechanism to a ramp input.

For a stable system, there must not be any roots of the characteristic equation in the right half of the complex s plane. A stable system usually has a pair of complex roots much closer to the imaginary axis than any of the other roots. These roots, known as the control poles, are largely responsible for the transient performance of the servomechanism. The controller may contain compensating networks which introduce

zeros to cancel undesirable poles and substitute desirable poles.

Transient performance is often given in terms of the output response to a unit step input—the response frequency, overshoot, and settling time being specified. A value of $\zeta = 0.4$ in the control poles usually limits the transient overshoot to 25 per cent.

Steady-state performance may be specified in terms of the steady-state error during a steady ramp input.

$$r(t) = \omega t$$

For a type I servomechanism ($n = 1$)

$$e_{ss} = \lim_{s \rightarrow 0} sE(s) \\ = \frac{\omega}{K_1}$$

For a type II servomechanism ($n = 2$), the steady-state error for a steady ramp input is theoretically zero.

Servomechanisms can be complicated systems with multiple loops, feedback functions, non-linear or time-varying components, adaptive elements, and undesired random-variable inputs. Special design techniques have been developed to handle these systems.

A very widely used design technique for linear servomechanisms is the Bode plot. The log modulus of the transfer function,

$$\text{Lm}[G(j\omega)] = 20 \log_{10} |G(j\omega)|$$

and the corresponding phase angle of $G(j\omega)$ are

plotted vs frequency on semilog paper. Straight-line asymptotic approximations for the log modulus plots are usually sufficiently accurate. The phase margin, defined as the amount of phase lag less than 180° of $G(j\omega)$ when $\text{Lm}[G(j\omega)] = 0$ decibels, is the basic design quantity. A phase margin of 45° corresponds to control poles with a $\zeta = 0.4$ and a 25 per cent transient overshoot.

A useful tool in the design and analysis of servomechanisms is the root locus plot. The loci of the roots of the closed loop characteristic equation are plotted as the gain is varied. The gain is adjusted until the control poles have a value of ζ corresponding to the desired transient response.

SHOCK WAVES

Infinitesimal disturbances in a fluid medium are propagated with a characteristic speed known as the sound speed. When the restriction on the amplitude of the disturbance is lifted, the linear approximation breaks down and the velocity of propagation becomes dependent on the amplitude of the disturbance. Another feature of this phenomenon is that the forward gradient of the disturbance rapidly steepens until it becomes a discontinuity and propagates as such. A *shock wave* is then a discontinuity in the physical properties of a fluid medium which propagates through

the medium at supersonic velocity without further change. The strength of the shock is defined by the Mach number, the ratio of its velocity to the undisturbed sound speed. Such waves are generated by the detonation of explosive material, by high-speed aircraft and missiles, and by earthquakes and similar natural phenomena.

Since all media are necessarily discrete, a true discontinuity is inconceivable but, as the thickness of the shock transition corresponds to only a few mean free paths in a gas (or internuclear distances in a solid), the transition can be treated as a discontinuity to the same extent that the medium can be regarded as continuous. In comparison with an adiabatic or isentropic change, the shock wave is an irreversible process and hence leads to an increase in the entropy of the material. The pressure, density and temperature of the medium are all raised on passage through the shock and the flow velocity is reduced. The latter is easily understood by observing that, with respect to the moving front, the molecules enter with an ordered flow motion at supersonic speed and the transport processes in the front transform a major fraction of this ordered flow into the random temperature or kinetic motions of the molecules.

The extent to which the various properties change through the transition depends on the magnitude or strength of the shock and on the thermodynamic properties of the fluid. For an essentially incompressible material such as a liquid or solid, the major change normally occurs in the pressure variable, whereas, for a gaseous medium, the most significant change is in the temperature. Although shock waves in solid and liquid materials have been used to study physical properties at high pressures, (see PRESSURE, VERY HIGH), the method is rather limited by the small test times available before the interaction of other wave phenomena which prevent the attainment of thermodynamic equilibrium, and it is in gases that shock waves have proved of most interest.

The detailed behavior of the shock transition is in itself a most important subject for study since shock waves are associated with the flight of supersonic aircraft and with the re-entry of ballistic missiles into the earth's atmosphere. In addition to their own intrinsic interest, shock waves are important for another reason. Since the transition involves the translational motions of the molecules, energy must eventually be transferred into other modes before the system reaches equilibrium. These subsequent RELAXATION processes involve the rotation, vibration, chemical reaction, electronic excitation and even ionization of the molecules if the shock is sufficiently strong. The shock phenomenon thus provides an excellent method for studying energy transfer processes. For chemical reactions in particular, the shock wave provides a source of heat which is essentially instantaneous and is completely homogeneous. Also, provided the thermodynamic properties of the medium are known, the temperature is completely defined by a determination of the shock velocity.

Although shock waves can be created in a large

number of ways, including the detonation of high explosives and the use of wind tunnels, the simplest technique makes use of the *shock tube*, discovered in 1899 by Vieille. A long tube of uniform cross section is divided into two parts by a thin diaphragm and gas is admitted to these at different pressures. If the diaphragm is ruptured in some way, a shock wave is generated in the low pressure gas and a corresponding rarefaction, or expansion, wave in the driver gas. Because the motion is restricted to a single dimension by the containing walls, the strength of the shock does not decrease with distance as it would in a three-dimensional expansion and the relaxation processes become simple functions of distance behind the front. This extremely simple piece of equipment can generate temperatures up to 20 000°K since the strength (or velocity) of the shock depends only on the pressure ratio across the diaphragm immediately prior to rupture and on the thermodynamic properties of the gases in the two sections.

The disadvantage of all shock tube work is that the front moves so rapidly and subsequent wave interactions follow so soon afterwards, that the available testing time is very short, often as low as 100 μ sec. In addition, the total quantity of gas involved is small so that detectors suitable for following the subsequent relaxation processes demand high time resolution and high sensitivity coupled with a suitable physical design which prevents any significant interference with the flow of the gas. Optical devices fit these requirements well, and interferometry, schlieren techniques, ultraviolet, visible and infrared spectrophotometry, and x-ray densitometry have all been used. At the highest temperatures, the shock heated gases become luminous and the shock tube has been used as a spectroscopic source to simulate conditions in stellar atmospheres.

Shock waves can also be created in highly ionized media where the forces are Coulombic in origin and the shocks are termed "collision-less." In this situation, shock waves lie more properly in the realm of plasma physics.

SIMPLE MACHINES

Over the years, the ability of man to think has enabled him to find new ways to perform laborious tasks. He developed the lever, ropes, and the inclined plane, modifications of which have resulted in the use of pulleys, wheels and axles, the wedge, and the screw.

Levers. A lever consists of a bar of nearly rigid material, either straight or bent, a fulcrum (F), a weight (W), and a force (P). The components F, W , and P can be applied, in any position relative to each other, to the bar as shown in Fig. 1. Levers are used to move large forces (weights) by means of smaller forces or are used to either amplify or diminish arc motion (Fig. 2). The arms A and B must be perpendicular to the lines of actions (directions) of their respective forces P and W . Then by a balanced moment equation about F,

$$PA = WB$$

FIG. 1.

FIG. 2.

The mechanical advantage of a lever, which defines the ability of an available force P to overcome a resisting force W is given by the ratio of W/P or A/B and results in the expression

$$\text{Mechanical advantage} = \frac{W}{P} = \frac{A}{B}$$

Figure 2 illustrates the use of a lever to amplify (or decrease) motion. When bar CG rotates about F, point G moves through the arc GH, and C will move through the arc CD and

$$\frac{CD}{CF} = \frac{GH}{FG}$$

Pulleys. In pulley systems, forces are transmitted by ropes used in conjunction with pulley wheels and axles. As noted from the lever examples, a wheel and axle is an adaptation of a lever rotating about its fulcrum.

Considering a frictionless system of pulleys, the force (pull) in any part of a continuous rope is constant and equal to P . Then, by establishing the number of supporting forces (ropes) and the weight W which is being moved, $nP = W$ where n is the number of supporting ropes. In Fig. 3, two forces (ropes) support the weight W , hence $2P = W$ and $P = W/2$. In Fig. 4, four forces (ropes) support the weight W , then $4P = W$ and $P = W/4$. In Fig. 5, five forces (ropes) support W , then $5P = W$ and $P = W/5$.

FIG. 3.

FIG. 4.

FIG. 5.

The mechanical advantage of a pulley system is the ratio of the weight to be moved to the applied pull in the rope or $W/P = n$, the same as the number of supporting ropes. In Fig. 3, $W/(W/2) = 2$ or for Fig. 4, the mechanical advantage is $W/(W/4) = 4$. In Fig. 5, the mechanical advantage is $W/(W/5) = 5$.

Pulley systems can be analyzed by the use of the work (refer to the section on WORK, POWER AND ENERGY) done by the force P and its relation to the work done by W . The displacement (in Fig. 4) of P is four times that of W . Then the work done by P is $4PS$ where $4S$ is the distance that P moves. The work done by W is WS . The mechanical advantage is $4S/S = 4$ and $4P = W$ as above.

Differential Pulley. The differential pulley makes use of two pulleys of different radii r_1 and r_2 attached to each other and rotating about a common axle. An endless chain connects the dual pulley to a second free pulley wheel as shown in Fig. 6. The chain and the corresponding

FIG. 6.

teeth on the dual pulleys prevent slipping between the chain and pulleys.

From the previous analysis of pulleys, a force equal to $W/2$ acts in the chain at points A and B. A moment equation about the axle C then gives

$$Pr_1 + \frac{W}{2}r_2 = \frac{W}{2}r_1$$

from which

$$P = \frac{W(r_1 - r_2)}{2r_1}$$

The mechanical advantage of the differential pulley is the ratio W/P .

The Inclined Plane. The inclined plane, as a simple machine, is presumed to be rigid and smooth. The weight (W), which moves along the incline, is a vertically downward force partially supported (N) by the frictionless plane. If the weight W is to be at rest on the incline, Fig. 7, the force system must be balanced in directions normal and parallel to the inclined plane. Balancing the forces parallel to the incline,

$$P = W \frac{h}{L} \quad \text{or} \quad PL = Wh$$

This is equivalent to a work equation where P is displaced a distance L and W is lifted a distance h .

When the force P acts to the left in a horizontal direction, P moves an equivalent distance of b , then

$$Pb = Wh$$

The mechanical advantage, as before, is the ratio $W:P$ or $L:h$ where the force is parallel to the incline. A wedge is equivalent in its analysis to an inclined plane. When t is the thickness of a wedge, $P:W::t:L$.

The Screw. The screw is an inclined plane wrapped around a cylinder in such a way that the height h is parallel to the axis of the cylinder.

FIG. 7.

If p is the height of travel in one circumference of the screw thread and r is the radius of the thread and friction is neglected, by the work method of analysis

$$P \cdot 2\pi r = Wp$$

The mechanical advantage is

$$\frac{W}{P} = \frac{2\pi r}{p}$$

Gears and Gear Trains. A gear is a wheel with projections uniformly spaced around its circumference. It is usually meshed with a second similar wheel of a different diameter so that the circumferential forces and rotational speeds are different. Figure 8 shows two meshed gear wheels, the teeth of which are not shown. From a balanced moment equation,

$$PR_1 = WR_1$$

then

$$\frac{W}{P} = \frac{R_1}{r_1}$$

and the mechanical advantage is the ratio of W/P or R_1/r_1 .

Gear trains consisting of more than two gear wheels have the same relationships. In Fig. 9, letting the wheels be represented by letters, then

$$PR_1R_2R_3 = WR_1r_2r_3$$

FIG. 8.

FIG. 9.

and the mechanical advantage is

$$\frac{W}{P} = \frac{R_1 R_2 R_3}{r_1 r_2 r_3}$$

By inspection and understanding that the points of contact, such as point H, have a common speed, the directional relations can be determined. If wheels B and C are rotating counterclockwise, D and E rotate clockwise, and F and G rotate counterclockwise.

Spur gears are those which have their teeth cut parallel to the parallel axes of rotation. Bevel gears are used when their axes of rotation intersect and have their teeth cut on the conical surfaces with their apex at the point of intersection of their axes. Their speed ratios are inversely proportional to their pitch diameters, number of teeth, or their number of revolutions. Referring to Fig. 9,

$$\frac{\text{rpm of } E}{\text{rpm of } F} = \frac{2R_3}{2r_2} = \frac{R_3}{r_2}$$

When a screw meshes with a cogged wheel, it is known as a *worm and worm wheel*. When the worm has a single continuous thread, one revolution of the worm will cause the wheel to rotate equivalent to a circumferential distance equal to the distance between two consecutive teeth. Thus a worm must rotate 48 revolutions if a worm wheel with 48 teeth is to rotate one revolution. The same relationship is true if speeds are considered.

Efficiencies of Simple Machines. The efficiency of a machine is defined as the ratio of the output to the input. The efficiency of a lever is relatively high since the only loss will occur at the fulcrum. Assuming a frictional moment of 5 per cent of the weight moment, then

$$PA = (W + 0.05W)B$$

and the efficiency (per cent) = $(W/1.05W)(100)$. For pulley systems, the efficiencies are rather low because of the frictional resistances at the pulley wheels. A "rule of thumb" states that the weight W shall be increased by 10 per cent for each wheel over which any rope passes. Thus if there are four pulley wheels, the efficiency (per cent) = $[W/(W + 0.4W)](100)$. Differential pulleys have efficiencies approximating 30 per cent due to the large amount of friction present. The efficiency of

an inclined plane is given by the expression

$$\text{Efficiency (per cent)} = \frac{h}{h + fb} 100$$

for the case where the applied pull tends to move the block up the incline (Fig. 7) and f is the coefficient of friction between the incline and the block.

JOHN W. BRENNAN

SKIN EFFECT

For a steady unidirectional current through a homogeneous conductor, the current distribution over the cross section is uniform. However, for an alternating current, the current is not uniformly distributed over the cross section but is displaced more and more to the surface as the frequency increases. For very high frequencies, practically the entire current is concentrated in a thin layer at the surface or "skin" of the conductor. This phenomenon has commonly come to be called the "skin effect."

For a physical explanation of this phenomenon, consider a cylindrical conductor that is carrying a steady unidirectional current. The current distribution over the cross section is uniform. A magnetic field is set up by the current in which the magnetic flux lines within and around the conductor are symmetrical to the conductor axis, i.e., they are in concentric circles. Consider the conductor to be composed of very small circular filaments of equal area which carry equal fractions of the total current. Consider a filament A near the axis of the conductor and another filament B near the surface. The flux linking A is greater than that linking B. If the steady unidirectional current is changed to an alternating current, the magnetic field which is set up by the current must reverse itself periodically with the result that the flux linkages change with time. Self-induced electromotive forces (emf's) are created within the conductor due to these flux changes. These emf's tend to generate currents (eddy currents) which oppose the main current. Because the emf created in filament A is greater than that in B due to a greater flux linkage, the net or resulting current in A becomes less than in B. The current in the conductor is no longer uniform but is displaced toward the surface. The current density becomes greater at the surface and decreases toward the center. This current displacement becomes more pronounced the higher the rate of change of flux.

The total resistance offered by the conductor to alternating current is greater than to a steady unidirectional current because of skin effect. When the current is displaced from the center of the conductor and crowded into the area near the surface, the effective cross section of the conductor is reduced, thereby increasing its resistance. The resistance of the conductor increases with frequency.

The equations which mathematically describe skin effect can be derived from Maxwells' equations for electrodynamic problems. However,

exact solutions have been obtained for only a few simple shapes of conductor. Shapes which have been amenable to analysis include the cylindrical conductor, tubular conductor, flat conductor, surface plated flat, cylindrical and tubular conductor, and coaxial conductor. Even then it is necessary to consider conductors whose material properties do not change with time or temperature.

The first theoretical explanation of skin effect for wires of circular cross section was given by Lord Kelvin in 1887. Early investigators were Kennelly, Laws, and Pierce,² who conducted comprehensive experiments on skin effect, and Dwight³ who obtained solutions for skin effect in tubular and flat conductors. Many other investigations have been made since that time.

The solution to the skin effect equation for a flat or plane conductor carrying a sinusoidal alternating current shows that the current density is maximum at the surface and decreases exponentially in magnitude with distance from the surface into the conductor. Also, as the distance from the surface increases, the current lags in time-phase further and further behind the current at the surface. A quantity $\delta = (2/\sigma\omega\mu)^{1/2}$ is often called the "skin thickness" since it corresponds to the distance from the surface in which the current density drops to $1/e$ of its value at the surface. In this equation, σ is the conductivity, μ is the permeability of the material, ω is the frequency. The resistance and internal reactance of the plane conductor are equal at any frequency. Also, the ac resistance of the conductor is exactly the same as the dc resistance of a plane conductor of thickness δ .

For a cylindrical conductor carrying a sinusoidal alternating current, the solution to the skin effect equation is found in terms of the zero-order Bessel function of the first kind. If the frequency is quite high, the exact formulation in terms of Bessel functions reduces to the simple exponential solution for flat or plane conductors. A useful engineering approximation for the ratio of ac to dc resistance is $R_{ac}/R_{dc} = a/2\delta$ where a is the radius of the conductor and $\delta \leq 0.1a$. The exact ratio in terms of Bessel functions must be used to obtain a solution for low frequencies or small conductors where $0.1a < \delta < a$. At radio frequencies, there is practically no magnetic field inside the conductor, so the reactance is negligible.

The solution to the skin effect equation for tubular conductors is expressed in terms of Bessel functions of the first and second kind. Since the interior portion of a cylindrical conductor carries very little current at high frequencies, thin tubular conductors are often used with a corresponding saving in material. At these frequencies, the tube acts like a solid conductor and effectively serves as an electromagnetic shield.

Conductors are often surface plated for specific applications. Since silver has high conductivity, resonant cavities and wave guides which operate at very high frequencies are silver plated to reduce I^2R loss since most of the current is concentrated

at the surface. Analyses have been made of a number of surface plating combinations to determine what effect such coatings have on the over-all resistance.

The skin effect phenomenon has a very practical application in induction heating. Since the current is concentrated near the surface, a highly selective heating source is created in the surface itself. Advantage is taken of this phenomenon and electromagnetic induction to create a heating method which requires no external heat source and no physical contact with the energy source, the induction coil.

Consider an induction coil carrying alternating current which is wound uniformly around a metal cylinder. Eddy currents are induced in the metal and tend to concentrate near the surface. The problem is similar to that of the cylindrical conductor previously described except that the induced currents are in concentric circles at right angles to the axis of the cylinder instead of being in the axial direction. The solution of the skin effect equation is in terms of the first-order Bessel function instead of the previous zero-order function.

SOLAR ENERGY SOURCES

The existence and persistence of biological life on our planet during the last two or three billion years informs us that the solar light intensity has been very steady for at least that length of time.

This in turn points to the fact that the source of solar power must be nuclear energy. Any other source (chemical, gravitational, etc.) would have been exhausted long ago.

The detailed mechanism responsible for solar energy production was identified some thirty years ago. The energy is liberated when, through various networks of reactions, four hydrogen atoms (H) are combined to form one helium atom (He). The difference of mass between the four hydrogen atoms and the helium atom ($\approx 5 \times 10^{-29}$ gram, corresponding to 26.740 MeV) is then liberated, mostly in the form of gamma rays (about 96 per cent, but also partly in the form of neutrinos (about 4 per cent). The gamma rays (γ) are quickly transformed into heat while the neutrinos (ν) escape immediately and are lost as far as solar heating is concerned.

Some 4.7 billion years ago the mass of gas which was to become the sun was somehow detached from a bigger mass and started to condense under its own weight. From the outside, the stellar mass looked red and was a lot more brilliant than the present sun. The particles composing the gas were mostly hydrogen atoms (about 90 per cent of the atoms), helium (about 9 per cent), then carbon, nitrogen, and oxygen (less than 1 per cent.) and finally traces of many other elements including some metals such as iron. As the contraction proceeded the gas grew hotter. When the temperature reached about one million degrees centigrade, thermonuclear reactions between the atoms in the gas started to occur and to liberate nuclear energy. As the power released by these reactions became comparable to the power radiated away by the sun, the contraction stopped, the temperature remained constant and nuclear energy took over the burden of keeping the sun warm. The period of contraction had lasted about 10^7 years. By then the sun had taken its present yellowish appearance and had approximately its present-day brilliance. It had become a so-called main-sequence star.

The transformation of hydrogen into helium then mainly involved the following set of reactions. First in a collision between two hydrogen atoms (H^1) a nuclear reaction takes place and an atom of deuterium (H^2 , heavy hydrogen) is formed. This reaction is by far the slowest that we shall meet. It essentially governs the rate of solar energy generation. Next the deuterium reacts with another hydrogen to form an atom of helium 3 (He^3 , the light isotope of helium); then two helium 3 thus formed react together to form one helium 4 (He^4) isotope and to release two hydrogen atoms. (The collision between helium 3 and hydrogen yields nothing.) The chain (called the proton-proton or PP I chain) is summarized in Table I.

As the concentration of helium increases, another reaction becomes important, the reaction between one helium 3 and one helium 4, resulting in the production of one beryllium 7 (Be^7) isotope. In this reaction, the beryllium atom captures a free electron in the stellar gas and decays into a lithium 7 (Li^7) atom. Then the

TABLE I. THE PROTON-PROTON CHAINS

γ represents gamma rays; ν represents neutrinos

lithium 7 atom captures a hydrogen atom, thereby forming a beryllium 8 (Be^8) atom. This atom is highly unstable. It rapidly breaks into two helium 4. This forms the PP II chain (see Table I).

In the present sun, 40 per cent of the energy comes from the PP I chain and 56 per cent from PP II. The central temperature is about sixteen million degrees and the central density 180 g/cc. (The density of water is 1 g/cc.)

A third chain is started if the beryllium 7 atom absorbs a hydrogen atom before it has time to decay. A boron 8 (B^8) atom is thus formed which quickly decays to beryllium 8. The beryllium 8 breaks apart releasing two helium 4 atoms. The contribution of this chain to the total energy generation is negligible (0.05 per cent). Its interest lies in the fact that with the decay of the beryllium 8, a neutrino (ν) with a mean energy of about 7 MeV is emitted. The other branches are also accompanied with neutrino emission but with mean energy less than 2 MeV. High-energy neutrinos are far easier to detect than low-energy neutrinos. Later we shall discuss a project already underway which should bring about the detection of solar neutrinos.

Finally, the fourth mode of hydrogen to helium conversion in the sun is the famous carbon cycle. First an atom of carbon 12 (C^{12}) captures hydrogen to produce nitrogen 13. Then nitrogen 13 (N^{13}) decays to carbon 13. Carbon 13 (C^{13}) forms nitrogen 14 (N^{14}) and oxygen 15 (O^{15}) by absorbing successively two hydrogens. Oxygen 15 decays to nitrogen 15 (N^{15}). Nitrogen 15 captures a last hydrogen and breaks into carbon 12 and helium 4. Carbon 12 is thereby returned to the gas, ready to start the cycle again.

Until a few years ago, this cycle was thought to be the main source of energy generation in the sun. Better solar models made with more accurate evaluation of the opacity of the solar material have shown that only about 4 per cent of the sun's brightness comes from this cycle.

As mentioned before, the sun has been in the process of converting hydrogen into helium for the past 4.5 billion years or so. Now the number of helium atoms in the center reaches 30 per cent from the 10 per cent that was there originally. As this number keeps on increasing, a bigger and bigger fraction of the solar energy will come from the carbon cycle. In a few billion years, as the core gets depleted of hydrogen, the sun will slowly start warming up again. A thin shell of hydrogen surrounding the helium core will get hot enough to generate energy, this time almost entirely through the carbon cycle. As this process goes on, the envelopes will start expanding at a rather fast rate; the sun will be entering its red giant phase. The surface, somewhat cooler than it is now, but still at temperature above the melting and vaporizing point of all material, will gradually swallow Mercury, Venus, the earth, and possibly Mars and Jupiter. Humanity will have learned to escape the doomed solar system or it will be destroyed. However since these events will take place in a few billion years, there is still time . . .

Eventually the central temperature will reach the one hundred million degree mark and the central helium will be ignited. The collision of two helium 4 nuclei induces the formation of one beryllium 8 atom which, however, soon breaks apart into its initial components.

However, as this sequence of combination and dissociation goes on (similar to processes in atomic and molecular gases), an equilibrium concentration of beryllium builds up. Occasionally one of these atoms will hit another helium 4 and form a carbon atom. The over-all reaction is labelled $3\text{He}^4 \rightarrow \text{C}^{12}$. It will provide energy for the sun for a few tens of millions of years.

Eventually, when helium is exhausted the sun will keep on warming its center and will burn its carbon and then its oxygen (both of these elements are products of the helium burning stage). Soon it will have no more energy sources to draw on. It will start cooling and contracting—first becoming a white dwarf, then shining no more, and losing all contact with the external world except through its gravitational field.

How and how well do we know that? What is the basis of our exploration of the past, the present, and the future of our sun? In our hands we have two different tools: physics and astronomy. Laboratory experiments are the foundation of our understanding of matter at our scale—the atomic scale and the nuclear scale. From these experiments, theories have been constructed which we believe can be applied in extraterrestrial settings. Astronomical observations are the basis of our cognizance of extraterrestrial settings.

From observations made on the sun we can obtain its mass, its radius, its luminosity, and the chemical composition of the surface. From other individual stars, we get even less information. However from statistical studies made on stars, and in particular on star clusters, we obtain most of our knowledge of stellar evolution (the same way one can investigate the pattern of growth of trees by walking in a forest).

The two main observational characteristics of a star are its color and its absolute brightness (i.e., how much energy it pours out). Families of stars of similar or related brightness and color have been identified for a long time. The most important groups of stars are called main sequence stars, red giants, and white dwarfs. After many years of patient labor involving the working out of stellar models from our knowledge of hydrodynamics, atomic and nuclear physics, and the comparison of these models with actual stars or groups of stars, the pattern of evolution has become apparent. After a period of contraction, a star spends most of its life as a main-sequence star (such as the present sun), then it becomes a red giant, and eventually after shedding out some of its mass, it becomes a white dwarf.

The story of our sun described in the first pages of this text is based on such evidences. How solid such evidences are, one never really is certain, but in view of the enormous amount of observations properly explained this way, one feels confident.

Another piece of information about the sun should become available within a few years. As mentioned before, a fraction of the solar energy is used to generate neutrinos. These neutrinos come from the hot furnace in the center of the sun and escape immediately. A program for the detection of these neutrinos has been underway for some time. The neutrinos are extremely difficult to detect and consequently the experiment is a highly involved one. If the experiment is successful, it will give us first hand information about the solar interior. First we shall get direct confirmation of the nuclear origin of solar energy; second we shall obtain a very accurate determination of the solar temperature. Should this measurement be very different from our present estimation we would have to worry about our knowledge of stellar structure and possibly be on the way toward exciting new discoveries.

SOLAR ENERGY UTILIZATION

The use of solar energy is likely to become of increasing importance both on earth, because of the rapidly diminishing supplies of fossil fuels, and in man's expanding adventures into space. The problem of economically using solar energy for various terrestrial needs has challenged us for many years, but there are still only a few economically attractive applications. Technological advances may well change this situation and help satisfy mankind's growing appetite for more and more energy. The launching of the first earth satellite opened up a completely new era for solar energy utilization. For space applications, reliability and weight are generally much more important than the cost of the power system itself. Silicon photovoltaic power supplies already have found extensive use on satellites and space vehicles.

The Sun as an Energy Source. Our sun is a typical main sequence dwarf of spectral class G-2. In almost every respect (size, luminosity, mass, etc.), it is an average star. The mean distance from the earth is 93 004 000 miles, at which distance the sun subtends an angle of 31 minutes 59.3 seconds.

The sun's total radiation output is approximately equivalent to that of a blackbody at 10 350 R (5750 K). However, its maximum intensity occurs at a wavelength which corresponds to a temperature of 11 070 R (6150 K) as given by Wien's displacement law. Figure 1(a) presents the intensity of solar radiation outside the earth's atmosphere as a function of wavelength. The total irradiance at the mean sun-earth distance is approximately 442 Btu/hr ft² (0.140 watts/cm²). Figure 1(b) shows how the energy in the sun's spectrum is distributed.

Sunlight passing through the atmosphere suffers both absorption and scattering. The solar irradiance reaching the earth depends upon the total air mass through which the sun passes and, of course, weather conditions. Figure 1(c) shows a typical plot of the solar irradiance at the earth's

surface. For some applications, the radiation from the sky is also important. The day sky exhibits wide variations in brightness and in spectral distribution, depending upon the sun's position, weather conditions, and the "receiver's" orientation.¹ Table 1 presents typical values of direct and diffuse solar radiation for several different atmospheric conditions. A great deal of study has been made of the variation of the solar irradiance at the earth's surface with weather, atmospheric conditions, zenith angle of the sun, etc.^{2,3}

Uses for Solar Energy. Table 2 lists most types of application of solar energy of interest today. They are grouped according to the form of energy required by the application. As an example, supplying electrical power for space vehicles requires a conversion from solar to electrical energy which may be a one-step process with photovoltaic cells (solar cells) or a multistep process. A typical multistep process might involve conversion of solar energy to thermal energy by using a parabolic mirror to heat a working fluid in a boiler, then conversion to mechanical energy using Stirling engine, and then conversion to electrical power using a generator. Reference 4 discusses each of these applications and comments on their economic feasibility. The interested reader is directed to this and other references listed at the end of this article for these details.

Considerations in the Conversion of Solar Energy to Other Forms. Table 2 indicates that most of the applications of solar energy require that the energy be delivered in one of four forms: thermal, electrical, mechanical, or chemical. It is of interest, then, to examine the techniques and limitations of converting solar energy to these other forms.

Table 3(a) shows several methods of directly converting solar energy to these other forms. Table 3(b) shows other conversion steps that might be used in a multistep process. The devices described in Table 3(b) make use of processes which are well known and not restricted to solar energy utilization. Those in Table 3(a), on the

lenses to achieve high flux densities (concentrating collectors) while others do not (flat-plate collectors).

Flat-plate Collectors. The most common flat-plate collector consists of a metal plate painted black on the side facing the sun and thermally insulated on the edges and back. Above the plate, spaced an inch or so apart, are one or more glass or plastic covers to reduce upward heat losses. The absorbed energy is transferred to water or some other working fluid in tubes which are in thermal contact with the absorber plate or by circulating air past the absorber. Figure 2 displays several flat-plate collector designs.⁵ Design B is the conventional type described above; A uses air instead of water for heat transfer. In C, the glass-shingle collector, heat is absorbed on the blackened bottom third of tilted glass plates

other hand, are of prime interest to the present discussion.

Conversion of Solar Energy to Thermal Energy. Many of the systems which utilize solar energy first collect the energy and its heat. A solar heat collector intercepts radiation, converting this to thermal energy, and transfers this heat to a working fluid. Some collectors use mirrors or

and transferred to the air drawn down through these shingles. In D, solar energy is absorbed on black gauze. The flat-plate collector is a simple, rugged device which, without orientation mechanisms, can efficiently collect solar energy at moderate temperature levels.

The results of some comparative calculations of conventional collectors are shown in Fig. 3. The emissivity and absorptance of the absorber plate was assumed to be 0.96, and the curves were plotted for zero, one, two, and three cover plates of typical single-strength window glass. It is seen that for high efficiencies (with correspondingly low collector temperatures), it might be preferable to have only one or two covers. As an example, a two-cover collector is preferable to a three-cover collector out to a temperature of about 200°F (for the case analyzed);

it is only at higher temperatures that the decrease in upward losses made by using one more cover is greater than the transmission loss of that cover.

Concentrating Collectors. An optical system using lenses or mirrors can be used to concentrate solar radiation into a very small area. If this energy is received into a cavity or absorbed on a metal plate, heat is generated and very high temperatures may be obtained.

The concentration ratio C is defined as the ratio of the flux density within the image of the sun formed by the optical system to the actual flux density reflected from the mirror. For a parabolic mirror, C is given by⁷

$$C = 46.1 \times 10^3 \sin^2 \theta \quad (1)$$

where θ is the rim angle of the mirror as defined by the sketch in Fig. 4. Figure 4 plots Eq. (1) and also a parameter called concentration efficiency which is defined as the ratio of the power received within the sun's image to the total power reflected by the mirror. For the parabolic mirror, the concentration efficiency is given by

$$\eta_c = \left(\frac{1 + \cos \theta}{2} \right)^2 \quad (2)$$

The concentration ratio and the concentration efficiency are strongly influenced by the geometric perfection of the mirror and the location of the absorber with respect to the focus of the mirror.⁸

Consider an example where the energy reflected from a parabolic mirror is collected by an ideal cavity receiver having an opening equal to the image diameter of the sun. The rate at which heat energy can be withdrawn from the cavity, P , can be calculated by subtracting the radiative heat losses from the input flux. The result is:

$$P = \eta_c A \left[rH - \frac{\sigma T^4}{c} \right] \quad (3)$$

where A is the projected area of the mirror, r is its reflectance and H is the solar irradiance. T is the temperature of the cavity. Figure 5 uses Eq.(3) to plot the ratio of P/A as a function of cavity temperature for several rim angles. The

FIG. 3. Calculated performance of flat-plate collectors showing effect of multiple glass covers.

FIG. 4. Concentration ratio and concentration efficiency as a function of rim angle for a paraboloidal reflector.

intersection of the curves with the abscissa show the maximum attainable temperature for various rim angles, corresponding to $P = 0$ in Eq. (3).

A variety of optical systems have been studied for use as solar concentrators with various absorbers.⁹⁻¹¹ The parabolic mirror-cavity receiver example, however, is indicative of the ultimate performance attainable.

Conversion of Solar Energy to Electrical Energy. The PHOTOVOLTAIC EFFECT, particularly in silicon, has become very important to solar energy utilization. In the silicon "solar cell," photons create hole-electron pairs by removing electrons from valence bonds. This occurs in the junction region between *p*-type and *n*-type silicon where the electric field causes a current to flow in the cell. Equilibrium is restored by charge flowing around an external circuit through a load resistor.¹²

Each silicon nucleus shares its four valence electrons with neighboring nuclei forming a stable tetrahedral crystal. In the junction region, most of the electrons are in the lower filled band, below the forbidden energy band. The electron may be thought of as either bound to a crystal lattice region or, with the addition of enough energy, free to move about and conduct electricity. The width of the forbidden region, or energy gap, represents the threshold energy necessary to remove an electron from the bound position to the conduction band. For silicon, it is approximately 1.1 eV. It follows that only photons of 1.1 eV or over can create hole-electron pairs in silicon. Higher-energy photons can create hole-electron pairs with the excess energy being dissipated as heat (see ENERGY LEVELS and SEMI-CONDUCTORS).

Since one hole-electron pair is created for each photon possessing sufficient energy to do so, the ultimate efficiency that might be achieved depends upon the threshold energy at which the hole-electron conversion takes place and upon the spectrum of the radiation. Figure 6 is the plot of the maximum power conversion efficiency as a function of threshold level. It assumes that all of the photons whose energy is greater than or equal to the threshold energy are converted into

Fig. 5. Maximum power output from an ideal parabolic mirror-cavity absorber as a function of operating temperature.

Fig. 6. Maximum solar conversion efficiency of an ideal quantum converter.

hole-electron pairs at the potential of the energy gap.*

Some of the factors which limit the efficiency in a practical cell include:

*Several schemes have been proposed to get around the band gap limitation by using three or more semiconductors sandwiched with the widest-gap semiconductor on top—utilizing the highest-energy photons, a medium-gap material using the next lower energy, etc. It has also been proposed that it might be possible to continuously vary the material so that a variable band gap is achieved. Other schemes which utilize dichroic mirrors to separate the spectrum into two beams of different spectral content to shine on two separate sets of cells with different band gaps have also been proposed.

- (1) Some hole-electron pairs recombine before they can be separated by the field in the junction,
- (2) Reflection losses from the front surface,
- (3) Loss due to electrical resistance within the cell,

- (4) Loss due to leakage across the barrier (diode current).

In full sunlight a good silicon cell will develop approximately 0.6 volt, open circuit, and will operate at a conversion efficiency of 10 to 12 per cent.

Figure 7 is a photograph of one of the solar panels used on the Ranger Spacecraft developed for NASA's Jet Propulsion Laboratory. The panel contains 72 strings of 68 cells each to provide 100 watts output at approximately 30 volts. The use of optical filters to cover the cells results in a lower cell temperature, hence higher efficiency, and provides improved resistance to radiation damage.¹³ It is also possible to improve the power output per unit weight of a solar panel by using lightweight mirrors to concentrate sunlight on the cells.¹⁴

Conversion of Solar to Mechanical Energy. Solar radiation incident upon a reflecting surface exerts a radiation pressure of approximately 0.8×10^{-4} dynes/cm² or 1.7×10^{-7} lb/ft². Although impractical for terrestrial applications, the use of radiation pressure for space propulsion (solar sailing) may prove to be worthwhile for some missions.¹⁵

Conversion of Solar Energy to Chemical Energy. It has been estimated that only a few tenths of a per cent of a year's supply of incident solar energy is stored in an average farm crop. Research into the mass production of algae has

FIG. 7. Ranger spacecraft solar cell panel. (Photograph courtesy Electro-Optical Systems, Inc.)

been directed toward tenfold greater yields; research in other types of plants, toward the end of increasing photosynthetic efficiency, is also being conducted.¹⁶

The existence of photosynthesis raises the hope that other photochemical reactions will be found which can be effectively used to obtain chemical energy from the sun. What is needed is a reversible endothermic photochemical reaction which can utilize a large portion of the sun's spectrum. Most photochemical reactions evolve heat instead of absorbing it, or they reverse so quickly that the energy is lost even during exposure to sunlight.

Water is photochemically decomposed into hydrogen and oxygen by ultraviolet light, though at very low efficiency.¹⁷ A fuel cell could be used to obtain electricity from the stored gases, or mechanical energy could be obtained in an engine. While this process is not presently of economic importance, it serves to demonstrate the possibilities. Unfortunately, 50 per cent of the sun's energy is at wavelengths too long to be of much use for photochemical reactions, since the energy per photon is too low. All molecules which undergo photochemical change have a minimum threshold energy required to create a bond rupture. If a quantum is absorbed with energy above this threshold, the excess energy is dissipated (as kinetic, vibrational, etc.) and usually does not contribute to the conversion to chemical energy. The maximum theoretical efficiency of conversion of solar to chemical energy can be evaluated with the help of Fig. 6 providing the cutoff wavelength is known.

At the present time, there is not one system known which comes close to fulfilling all of the requirements for the ideal energy converter; however, important advances are being made and some chemical systems show a great deal of promise.¹⁸

SOLAR PHYSICS

The main activity of solar physics is the interpretation of the observed flow of energy away from the sun. Most of the sun's energy output appears as a nearly constant flux of electromagnetic radiation in the photographic, visual, and infrared regions of the spectrum, but extraordinary variations are characteristic of the x-, ultraviolet, and radio radiation. A small part of the sun's energy flows outward in highly variable streams of particles (mainly protons and electrons). Since the sun appears as a rather large disk, the observations forming the bases for the solar physicist's interpretations often refer to small areas of the solar surface, as well as the integrated radiation and particle streams from the entire sun. A reasonably good solar telescope can subdivide the apparent disk of the sun into about three million smaller elements of area. Streams of particles and radiation from each of these elements should be recorded, with all possible detail and precision, nearly continuously for a complete observational record. A close approach to such

observational perfection probably is unattainable, perhaps it is unnecessary, but the fragmentary and incomplete nature of all solar observations continues to be a serious barrier in the search for a satisfactory general theory of the sun. Some progress has been made, but until an adequate theory is developed, it is best to consider the physics of the sun by reviewing the observations of possible importance.

The radius, mass, and luminosity of the sun are fundamental in the physical interpretation of the sun. Luckily, they can all be deduced with reasonable directness from observations. In principle, the radius of the sun can be obtained directly from angular and linear observations made on earth, but a number of practical difficulties limit the attainable precision. Somewhat devious methods, invoking gravitational theory, give more consistent results that converge on the value,

Radius of the sun, $R = 6.9598 \pm 0.007 \times 10^{10}$ cm

The mass of the sun is also derived from the application of gravitational theory: first, to the measurement of the mass of the earth; then, by way of the moon and planets, to the sun; with the result,

Mass of the sun, $M = 1.989 \pm 0.002 \times 10^{33}$ gram

A measurement of the total radiation received at the earth's distance from the sun is the basic observation from which its luminosity can be found (once the distance to the sun, and the radius of the sun are known). This measurement is extremely difficult and is seriously distorted by the earth's atmosphere, but the value

Luminosity of the sun, $L = 3.90 \pm 0.04 \times 10^{33}$ ergs/sec

can be derived from long, independent series of observations.

An additional parameter, or series of numbers, is essential for the construction of an adequate theoretical model sun. These are the abundances of the chemical elements. For convenience, abundances are stated in terms of the abundance of hydrogen. In the sun, the relative abundances of the important constituents are

Hydrogen = 1.00	}	Q, the relative chemical abundance
Helium = 0.23		
Z (all other elements) = 0.02		

The values of L , M , R , Q , deduced from observation for the sun, are somewhere near the middle of ranges of these quantities as derived for other stars. It is, therefore, sometimes said that the sun is an average star, but for the stars inside an imaginary spherical shell surrounding the sun, with a radius so small that it is reasonably certain that all stars within the enclosed volume have been observed, a different interpretation is valid. Most of the stars close to the sun are cool, red, dwarf stars, probably the most numerous of all stellar varieties. Only ten of the fifty-five

nearest stars can be seen with the eye alone. Only three of these stars are brighter than the sun, most are exceedingly faint. Stars brighter than the sun are extremely rare, and the sun is outstanding in all of its properties.

Although the sun's L , M , R , and Q can be fitted into a coherent physical theory which, starting with a nuclear energy source (see SOLAR ENERGY SOURCES) near the sun's center, can trace the outward flow of energy from the deep interior, through complicated transformations, until a quantity and quality of radiation is predicted at the solar surface that agrees closely with observation; only the most primitive beginning has been made on a theory of the phenomena that occur in the observable regions of the sun: the photosphere, the chromosphere, and the corona.

The photosphere of the sun is the surface observed directly by the eye through a protective dense black glass screen. In very transparent skies with the help of special telescopes or at times of total solar eclipses, the chromosphere and corona may also be observed visually. All three of these layers show structures in widely different sizes and rates of change. The theoretical problems connected with the photosphere-chromosphere and the chromosphere-corona interfaces are nearly intractable, and the individual layers are understood only slightly better.

Nearly three centuries of telescopic observation of the solar photosphere define this part of the sun as that imaged on a photographic plate, or seen by the eye, using the light in a spectral band at least 1000\AA wide, centered near 5000\AA in the blue-green part of the spectrum. The portion of the sun thus recorded is a spherical shell, 5×10^8 cm thick, whose outer radius is the edge of the apparent solar disk, 7×10^{10} cm from the sun's center. Good photospheric photographs show a granulation composed of small (10^8 cm, or less) bright, circular, or hexagonal, structures all over the sun except extremely near the edge. These are the tops of convection cells that carry much of the solar energy. They are a few hundred degrees hotter than the five-thousand-plus degrees absolute that is consistent with the sun's assigned total luminosity. Occasionally, small dark spots (pores) appear among the granulations, and still more infrequently, a pore will develop into a larger dark complex, a sunspot region. Spot regions are some thousands of degrees cooler than the granulated photosphere in which they are immersed. They mark the locations of sizable magnetic fields, and the spot regions may cover some tenths of the sun's disk. Since the spot regions are nearly fixed on the solar surface, they may also be used as markers for the measurement of the rate of rotation of the sun.

The angular rate of rotation, deduced from sunspot, or spectroscopic, observations, varies from the sun's equator to its poles. It is greatest on the equator, there corresponding to a period of rotation of twenty-five days. At the pole the period of rotation is nearly thirty-five days.

Sunspots are the main sources of difficult problems of the photosphere. How can the

refrigeration of the spot regions be explained? What is the origin of the magnetic fields? How is the distribution of angular velocities established, and how is it maintained?

The chromosphere is most easily observed at times of total solar eclipse. It appears as red-purple narrow irregular ring just after the beginning and again just before the ending of totality. The average thickness of the chromospheric layer is 10^9 cm, but it is so tenuous that it is undetectable under conditions satisfactory for observation of the photosphere. For the daily observation of the chromosphere, a filter transmitting a spectral band not wider than 1\AA must be used to produce monochromatic solar images, and the center of the spectral band transmitted by the filter must be adjusted to coincide with the center of an emission line that appears strongly in the spectrum of the chromosphere. Nearly all observations of the chromosphere are made with light from the center of just two spectrum lines: the H-alpha line of hydrogen in the red part of the spectrum; and the K line of ionized calcium in the ultraviolet. The pictures show the chromosphere as a continually seething part of the solar atmosphere, subject to spectacularly sudden changes in the neighborhood of sunspots. The changes in the chromosphere and the dominating changes that occur in the underlying sunspots are considered together as the phenomenon of *solar activity*.

Long before regular observation of the chromosphere became possible, records of the numbers of sunspots had led to the discovery of a ten-year cycle of variation. As solar observation has become more nearly continuous, nearly every aspect of the sun's activity has revealed cyclical behavior closely synchronized with the variation in the numbers of spots. This is especially true for the changes in the chromosphere. The solar flares and extensive systems of solar prominences in the chromosphere are apparently organized and controlled by the magnetic fields rooted in the sunspot regions.

However, the smallest structures in the chromosphere are not obviously connected with sunspot activity. The smallest features in undisturbed solar areas far from the dominance of spot regions undergo damped oscillations that are nearly periodic with characteristic times about three hundred seconds. Perhaps these motions are enforced by the somewhat slower changes observed in the photospheric granulations on which the chromospheric structures are based.

Like the chromosphere, the corona can only be observed with the unaided eye at the time of a total solar eclipse, but with telescopic, spectroscopic, and other instrumental aids, it can be observed every day. It is the most extensive of the divisions of the sun's atmosphere, its outer limits lying somewhere beyond the distance of the earth from the sun where the corona becomes indistinguishable from the interplanetary medium. The corona changes both gradually and suddenly in rather sensitive connection with the spot regions. It is the principal source of the sun's x-rays, extreme ultraviolet, and radio emission,

and the combination of satellite observations near the short-wavelength limit of the solar spectrum and radio observations at the other end of the spectrum results in an attractive qualitative picture of solar activity.

At times of solar flare outbursts in the spot regions, observations in the two ends of the solar spectrum can be interpreted as indicating motion of an unknown disturbance, starting away from the sun with the beginning of the flare and moving outward through the chromosphere and the corona. Frequently, streams of particles associated with the flare activity reach earth, and are detected as cosmic rays and by their secondary effects such as terrestrial magnetic storms, but many of the changes induced in the corona by activity in spot regions seem to be connected with variations in local solar magnetic fields and not with streams of particles.

It should be evident from this brief synopsis of some of the general results of intensive observation of the sun for more than a century that solar theory is in a reasonably satisfactory state only for those parts of the sun that have not been observed. The problems for which theoretical help is badly needed to understand observed phenomena are derivatives of two main questions that are not necessarily unrelated: (1) What is the explanation of the observed variation of angular rotation from the sun's equator to its poles? (2) What are the physical bases of sunspot phenomena? When it is realized that not a single first-class spectrum of a sunspot exists, it is clear that remarkable opportunities in both observational and theoretical solar physics remain unexploited.

SOLID-STATE PHYSICS

Solid-state physics is the study of the crystallographic and electronic properties of solids, primarily of crystalline solids. It concerns itself with both the theoretical and experimental aspects of solids. Theorists attempt to apply both classical and quantum mechanical principles to the basic understanding of the nature of solids; experimentalists apply an enormous range of experimental techniques to the study of the properties

of solids. It is a broad field, merging with such associated disciplines as chemistry, metallurgy, ceramics, and electrical engineering; the boundaries between solid-state physics and these disciplines are not well defined.

The atoms of which a given solid is composed can be considered, for many purposes, to be hard balls which rest against each other in a regular repetitive pattern called the crystal structure. Crystal structures have a wide range of symmetries. Most elements have crystal structures of high symmetry; many compounds have complex, crystal structures of low symmetry. The determination of crystal structures, atom placement and the orientation dependence of numerous physical properties is an absorbing study, one which has occupied the lives of numerous geologists, mineralogists, physicists and other scientists for many years (see CRYSTALLOGRAPHY).

The hard-ball model of solids just described is too simple to explain many properties of solids. That solids can be deformed by external forces and that atoms in a solid possess vibrational energy imply deformability of the atoms, an attribute often built into the model by the assignment of springs to connect the atoms to their nearest neighbors. This ball-and-spring model has many successes, one important early use was that of Einstein to devise a reasonably successful quantum mechanical theory of specific heats.

The perfect crystal, one with all atoms on precisely defined lattice points, is nonexistent. By the way in which crystals are produced, either in a laboratory or by nature, defects in structure exist, often in profusion. These defects may be categorized by their geometry and size.

All crystals have atoms which occupy external surface sites and which do not have the correct number of nearest neighbors as a consequence. This surface is a seat of energy and is characterized by a SURFACE TENSION. Furthermore, internal surfaces exist, grain boundaries and twin boundaries, across which atoms are incorrectly positioned. In a crystal of reasonable size, say 1 cc, these two-dimensional defects, called *surface* defects, contain only about 1 atom of the solid in 10^6 , a rather small fraction.

Defects with extent in only one dimension are called *line* defects. The most prominent of these, the dislocation, is a line in the crystal along which the atoms have either an incorrect number of neighbors or neighbors which have not the correct distance or angle. In any cross section of a real crystal, one might expect to find a density of dislocations from 10^{11} to nearly zero per square centimeter.

Defects which have extent of only about an atomic diameter also exist in crystals—the *point* defects. Vacant lattice sites may occur; they are called vacancies. Extra atoms—interstitials—may be inserted between regular crystal atoms. Atoms of the wrong chemical species, impurities, may also occur.

The energy of the various defects is of concern to physics. The energy necessary to separate the

atoms of a solid into neutral, non-interacting atoms, the sublimation energy, is about 81,000 cal/mole for a typical solid, Cu, at room temperature. This is about 3.5 eV per atom. Surface energies, both of grain boundaries and free surfaces, are of order 1000 ergs/cm², about 2 to 10 eV per surface atom. Dislocation energies are of similar size per atom along the dislocation, 2 to 10 eV per atom, so the energy of a dislocation is some 10^{-3} to 10^{-2} ergs/cm of length. The energy necessary to produce a vacancy in Cu is about 1 eV, that necessary to produce an interstitial about 2 to 3 eV. Since energies of these magnitudes are much more than kT per atom at reasonable temperatures, defects can be produced only by conditions which exist during the manufacture of crystals, by external means such as plastic deformation or particle bombardment, or by decided fluctuations in thermal energy away from the average. The amount of energy which is bound up in defects is not large compared with the total thermal energy of a solid at ordinary temperatures. All the vacancies in equilibrium in Cu even at the melting point comprise less than 10 calories of energy per mole, much less than the enthalpy at 1357 K of more than 7000 cal/mole. Similarly, the total energy of the free surface of a compact block of 1 mole of Cu is less than 10^{-3} calorie.

Crystallographic defects do not remain stationary in the crystal, but they move about with time. Some of these movements serve to reduce the over-all free energy of the solid, others (these are chiefly movement of the point defects) may simply be the wandering of random walk. Since the defects move, in general, over a potential barrier large compared to kT when they move from one equilibrium site to another, their rate of motion is controlled by rather large fluctuations in energy. Consequently their rate of motion depends on temperature through an exponential factor $\exp(-\Delta H/RT)$, where ΔH is the enthalpy increase when the defect moves from the equilibrium site to the maximum in the barrier.

Defects are extremely important in controlling many properties of solids, in spite of the relatively small number of defects which exist in most solids. Such properties as the behavior of solids under mechanical stress; mass, heat, and charge transport; and a host of electrical phenomena are extremely sensitive to the presence of particular kinds of defects.

The electronic structure of solids is determined, in principle, solely by the electronic structure of the free atoms of which the solid is composed. Precise calculation of the electronic structure of a solid is, however, a difficult task, one that cannot be done for the general solid. Nevertheless, by using approximate models, many general features of the electronic structure can be deduced, especially when close interplay of theory and experiment is established. As for the crystalline structure of solids, two stages are useful in understanding the electronic structure. First, the perfect electronic structure is defined; then irregularities in this structure, termed defects, are

described. Although both the geometry and energy of crystalline defects are defined, description of the geometry of many of the electronic defects is not possible, and one must be content in such cases with description of the energy of the defect.

The electronic structure of the inner electrons of atoms in a solid is little different from that of the corresponding electrons in free atoms. The ENERGY LEVELS of the valence electrons are modified tremendously, however. The state functions of these outer electrons extend over the entire volume of the solid, and restrictions of quantum mechanics force the electrons to occupy a set of discrete but tightly packed energy levels. This *band* of levels has an extent of several electron volts. Importantly, unoccupied levels for the free atoms are also split into bands for the solid. The basic electronic nature of solids is determined by the position in energy of the lowest unoccupied levels relative to the highest occupied levels.

The solid is called a *metal* if excitation of electrons from the highest filled levels to the lowest unoccupied levels can occur with infinitesimal expenditure of energy. Metals have a high electrical conductivity, σ , and $d(1/\sigma)/dT$ is positive; they also have high thermal conductivity and are opaque to visible light. All of these properties are a result of the ease of excitation of electrons by external means.

Solids for which the lowest unoccupied levels lie several electron volts, say 2 or more, above the highest occupied levels are called *insulators*. They have low electrical and thermal conductivity (relative to the metals) and are transparent to visible light.

Semiconductors are solids which are intermediate in properties between the metals and the insulators. For them, the energy gap between filled and unfilled states lies in the range 0.1 to 1.5 eV.

In insulators and semiconductors, some electrons can be excited by thermal means from the occupied levels (the valence band) into the unoccupied levels (the conduction band) leaving behind an unoccupied state, called a hole, in the valence band. Such electron-hole pairs can also be produced by electromagnetic radiation of proper frequency. Both the excited electrons and the holes contribute to electrical conductivity in these crystals. Excited electrons and holes exist in metals too, but they are not necessary for conductivity in the metals.

Crystallographic defects, in general, are also electronic defects. In metals their most important role is to provide scattering centers for electrons. In semiconductors and insulators, however, the crystallographic defects can produce an almost limitless variety of conductive and optical phenomena. The crystallographic defects, virtually stationary in the crystal, provide sites in the crystal which have well-defined charge geometry in contrast to the highly mobile electron-hole pairs.

Just as crystallographic defects control many important properties which depend on mass transfer, so do electronic defects control many

important properties which depend on charge transfer. In fact, the entire technology of devices made of semiconductors and insulators is based on proper control and distribution of defects (including impurities).

MAGNETISM, also a proper subject of solid-state physics, is basically an inherent property of the perfect crystal. DIAMAGNETISM and PARAMAGNETISM, largely of academic interest, are little influenced by defects (except for such special properties as electron spin resonance). The basic properties of ferromagnets (Curie temperature, saturation magnetization and magnetostriction) are inherent properties of the perfect lattice. The technological application of ferromagnets, however, demands careful control of defects, which exert strong influence on such properties as hysteresis loss, permeability and coercive force (see FERROMAGNETISM).

Summarizing in a sentence: solid-state physics, in its broadest sense, is the study of the perfect and imperfect crystalline and electronic structures and properties of solids, ranging from attempts to understand these phenomena from the most fundamental point of view to the edge of the technological application of solids.

SOLID-STATE THEORY

True solids possess long-range order not found in other phases of matter. The (approximate) periodicity of the potential in solids makes possible detailed investigations by powerful mathematical techniques which cannot be used in other condensed systems. Studies of phenomena related to the almost periodic potential comprise the bulk of modern solid-state theory. Research on gross deviations from periodicity, "imperfections," constitutes a sizable minority activity.

The one-electron problem in a truly periodic potential can be considered solved, in principle, with one reservation. Fast digital computers make the calculation of the "band structure," i.e., the dependence of electron energy on wave vector, $\epsilon(\mathbf{k})$, a matter of half an hour on the computing machine. (A few years, perhaps, is required to

develop a "program" capable of treating any crystal structure and potential.) The reservation refers to the uncertainty in knowledge of the potential to be furnished to the computing machine. Self-consistent methods have been constructed, but the treatment of "exchange" is not completely satisfactory.

Of course, electrons in a solid *do* interact, and a one-electron theory can not describe the correlation effects. Many-body theory is becoming increasingly important, and the collective behavior of the electrons is being investigated in various ways. Several types of cooperative phenomena are undergoing study.

The basic calculation of the dispersion of PHONONS (quanta of the vibrational field), i.e., the frequency of normal modes of oscillation vs their wave vectors, $\omega(\mathbf{q})$, is not as simple as for the electrons in a periodic potential. Not only are the interatomic forces difficult to specify, but there exist peculiarities, indeed singularities, in the density of states. Phonons also interact with each other, since the vibrational motion is not truly harmonic. Considerable activity is currently associated with these problems.

More difficult still are the questions which arise when the electron system and the phonons interact. Most theoretical work on pure systems is based on (1) a description of the electrons as if the potential were actually periodic, i.e., as if no phonons or even zero-point vibration were present, and (2) a description of the lattice vibration which ignores the electronic state of the crystal. For many purposes, this approximation is not as crude as it appears at first sight; if the electronic wave function actually is coherent over many atomic positions, and frequently it is, then the lattice vibration is indeed insensitive to small changes in the electronic state, and vice versa. Thus in a metal under ordinary conditions, one may ignore not only any change in the dispersion curve, but also any effect on the distribution function of phonons as the electronic state is changed, say by an electric field. In a semiconductor like Ge, the "phonon drag" problem may require that the electron and phonon distributions in the presence of a driving force be considered self-consistently, even though $\epsilon(\mathbf{k})$ and $\omega(\mathbf{q})$ may be treated as unchanged. Even this problem is not simple.

When imperfections are present, such as vacancies, impurities, dislocations, etc., it is necessary to consider the possibility of localized modes being created in the vicinity of these imperfections; that is, modes of lattice vibration of frequency ω may exist near the imperfections which could not exist in the perfect crystal. Furthermore there may occur a concentration of lattice modes of vibration in a certain frequency range, in the vicinity of the imperfection.

In addition, in some systems such as ionic crystals, it is necessary to go one step further, and consider "relaxation" of the lattice as an imperfection changes its electronic state. The motion of the neighboring atoms leads to a change in the electronic wave function, which in turn

may induce a change in the vibrational spectrum. Thus the simple Einstein relationship between absorption cross sections and emission transition probabilities must be modified, for example.

In the perfect crystal there exist simple selection rules based on momentum conservation which relate the initial and final values of the wave vector of the excited electron upon optical excitation. In the simplest case they are equal, except for the very small value of the wave vector of the incident photon. In many cases, however, there exists the possibility of "indirect" transitions, in which a phonon is simultaneously excited or absorbed. The probability of these transitions is reduced by a few orders of magnitude from that of direct transitions, but they are still observed and very important in macroscopic crystals. Theory has also developed to account for numerous new effects in optical properties of solids, such as nonlinear optical effects, laser action, 2-electron transitions, and 2-photon effects.

Magnetic behavior has received increasing attention in recent years. Nuclear and electron resonance phenomena have been powerful techniques for investigating the structure of solids (see MAGNETIC RESONANCE). Furthermore, the use of high magnetic fields has elucidated phenomena which were not capable of being investigated earlier. The theory of these phenomena has kept pace with them, if not preceded them. The theory of FERROMAGNETISM continues to occupy a major field of activity. The specific interaction among electrons which gives rise to the ferromagnetic behavior is not identifiable for a given system, although the general outlines of the theory are reasonably well understood.

The mechanical properties of solids are now understood at a far more fundamental level than they were a decade ago, through development of the theory of dislocations. Many new phenomena have been interpreted or predicted, such as spiral growth, "climb," dislocation networks, "whiskers," decoration with colloidal particles, etc. This has been a most active field of research (see SOLID-STATE PHYSICS).

In the theory of transport phenomena there are attempts at more sophisticated theory than the conventional one-electron Boltzmann equation will allow. Density matrix methods are applied, for example, and scattering probabilities are computed without making use of such approximations as spherical energy surfaces, Born approximation, etc., and the importance of Umklapp processes is now better appreciated.

Major changes in the theoretical techniques that have occurred recently are the use of fast computing machines, of course, as well as the increasingly widespread application of group theoretical methods. Green's functions and field theoretical methods in general also are appearing more and more in the literature.

The concept of quasi particles is now widespread, and we have names for helicons, excitons, magnons, phonons, polarons, plasmons, etc. Much modern theory is devoted to considerations

of the existence and the propagation of these quasi particles.

The existence of SUPERCONDUCTIVITY, which represented such a mystery for so long, has now been explained in terms of electron-phonon interaction. At present, people are trying to see if other interactions could likewise give rise to the existence of superconductivity. There is some speculation that high-temperature superconductors might exist.

Work on solid-state theory is widespread. Notable is the work in the United States, the Soviet Union, Japan, and England, but many other localities are contributing also.

SONAR*

The term *SONAR* is a coined word derived from the phrase *SOund NAvigation and Ranging*. The term generally refers to the principles employed in the design and operation of systems that utilize acoustic energy transmitted in an ocean medium; while the systems themselves are referred to as sonar systems. Thus, sonar may be defined as a branch of applied acoustics concerned with the utilization of the ocean as the transmitting medium.

The problem of sonar is threefold: (a) understanding the transmission of acoustic energy through the transmitting medium, (b) developing sources which convert mechanical or electrical energy into acoustic energy, and (c) developing receivers which convert the acoustic energy back into mechanical or electrical energy.

Whenever a body vibrates in a fluid, longitudinal waves are formed, which propagate outward from the vibrating body. The particles of the fluid are set in motion, and temporary stresses are produced which increase and decrease during each vibration. The motion of the particles gives the fluid kinetic energy while the stresses induce potential energy. The sum of the two energies is called acoustic energy.

Traditionally, the starting point for a discussion of the transmission of acoustic energy in a fluid is to assume a point source radiating acoustic energy in an ideal homogeneous nonabsorptive

* The opinions and assertions contained herein are the private ones of the writer, and are not to be construed as official, or as reflecting the views of the Navy Department or the Naval Service at large.

medium of infinite extent. Under these assumptions, the energy from the source will radiate outwards with the wave front forming a spherical shell. As the radius of the shell increases, the sound intensity decreases. In practice it is customary to express the sound intensity by means of a logarithmic scale. The most generally used logarithmic scale is the decibel. The intensity level in decibels of a sound of intensity I is defined as $10 \log (I/I_0)$ where I_0 is a reference intensity. The intensity level can also be expressed as $20 \log (P/P_0)$ where P is the pressure and P_0 the reference pressure, usually 1 dyne/cm^2 in underwater acoustics. In this discussion the terms in all equations are expressed in decibels. The decrease in intensity as the shell increases in radius is called the spreading loss. The spreading loss from a unit range of R_0 to a range of R is $10 \log [(I_{\text{intensity at } R_0}) / (I_{\text{intensity at } R})] = 10 \log (R^2 / R_0^2) = 20 \log R$. In most applications the use of such a simple model has been inadequate.

A more realistic model considers the following factors: the water-earth interface (bottom), the water-atmosphere interface (surface), the absorption of acoustic energy in the medium, the presence of foreign material in the medium, and the distribution of sound velocity. Considered as an acoustic medium, the waters of the ocean form a thin layer on the earth's surface. Some of the acoustic energy radiated into this layer by a source will reach either the surface or the bottom. At either of these surfaces abrupt discontinuities in acoustic properties occur. Because of these discontinuities part of the intercepted energy is reflected, part may be transmitted across the interface, and part may be scattered within the medium. Since the transmission of an acoustic wave in water is accompanied by a compression and expansion of the medium, friction will occur between water molecules. This friction results in the conversion of some of the acoustic energy into thermal energy. In addition to this frictional, or viscous, loss there is another loss of energy in seawater related to the salts which continuously undergo chemical changes because of pressure fluctuations. Energy losses associated with both of these phenomena are called absorption losses. Due to the presence of foreign bodies in the volume of water, reflection and scattering is not limited to the surface and bottom boundaries. Foreign matter and biological content vary widely in size and acoustic characteristics. All ocean waters contain such bodies which modify the direction in which the acoustic energy is transmitted. In sufficient number they may also modify and increase the total absorption loss. The effect of variations in sound velocity is to bend the wave front in the direction of the lower velocity. This bending of the wave front is referred to as refraction. Both refraction and reflection can result in the guiding of acoustic energy in certain directions.

The factors above affect the propagation of acoustic energy in seawater in two different ways. The first results in a spreading loss already mentioned, and the second results in a loss

referred to as attenuation. Attenuation consists of both the scattering and absorption losses. The spreading and attenuation are related to the distance the acoustic energy travels in different ways. An important difference is that the spreading loss frequently is relatively independent of frequency while the attenuation is a function of frequency.

There are three basic types of sonar systems: direct listening systems, echo-ranging systems, and communication systems.

In direct listening the acoustic energy is radiated by the target, which is the primary source. The acoustic transmission is a one-way process. In their more elementary forms direct listening sonar systems may be nondirectional and only give a warning that a primary source is in the vicinity of the searching vehicle; or directional, and permit determination of the bearing of individual primary sources relative to the listening platform. They generally do not give range. Direct listening is limited by the magnitude of the signal when it reaches the receiving point and the magnitude of the interfering noise which tends to obscure its reception.

In echo ranging, the sonar system projects acoustic energy into the water with the expectation that this energy will strike a target and enough of the energy will be reflected back to the searching platform so that it can be recognized as a target echo. The primary source of acoustic energy is in the searching platform, with the target, upon reflection of the energy, becoming a secondary acoustic source. The transmission of the energy is a two-way process. Echo-ranging sonar systems permit a determination of the bearing of a silent target, and by timing the echo-signal transmission and by knowing the velocity of sound in seawater, a range may also be obtained. Echo ranging is limited by the relative magnitudes of the signal and of the locally generated interference. In some cases the sonar performance is limited by reverberation, which is the acoustic energy returning by reflectors other than the target of interest.

Acoustically, sonar communications systems are similar to direct listening systems in that they utilize a one-way transmission path. Instrumentally, they are similar to echo-ranging systems, one located at each of the two points between which communications is to be established. In these systems coded pulses or voice modulated signals are transmitted by one system and received by the other.

To hear a target by direct listening, it is necessary that the acoustic level of the target less the transmission loss along the acoustic path from the target to the listening equipment be equal to or greater than the level of the background noise. This may be expressed as $L - H \geq N$ where L is the source level of the target, H is the one-way transmission loss, and N is the noise level. The size of this inequality depends upon operator skill, signal processing, and method of presentation. It is called the signal excess, E . This inequality can be written as an equation where $E = L - H - N$. This equation is called the direct-listening sonar

equation for an omnidirectional listening hydrophone. When using directional hydrophones a factor called the directivity index must be added to the right-hand member of the equation. The source level, L , is a measure of the amount of acoustic energy put into the water by the target vehicle and is equal to $10 \log$ (sound intensity at unit distance from the source). The transmission loss, H , is the sum of the losses related to refraction, surface and bottom reflection, absorption, and scattering. The noise, N , results from unwanted acoustic energies arriving from many different sources and normally consists of thermal, ambient, and self noises.

To see a target by echo ranging it is necessary that the acoustic level of the primary source less twice the transmission loss along the acoustic path from source to target plus the target strength be equal to or greater than the noise. This may be expressed, for a nondirectional receiver against a noise background, as $L - 2H + T \geq N$ where T is the target strength, a function of the reflecting characteristics of the target. Against a reverberation background the inequality becomes $L - 2H + T \geq R$ where R is the reverberation level. As in the case of direct listening, the inequalities can be expressed in terms of the signal excess as $E_N = L - 2H + T - N$ or $E_R = L - 2H + T - R$ where E_N and E_R are the signal excesses for noise and reverberation. The noise, N , comes from own-ship's noise and target noise. Reverberation, R , is the energy that is returned from the outgoing acoustic energy to the receiving equipment after having been reflected from reflectors in the medium other than the target. Reverberation sources usually are backscattering from the surface, bottom, and foreign particles in the water.

SPACE PHYSICS

Space physics is usually taken to be the physics of phenomena naturally occurring in space, but frequently space is not clearly defined. It normally includes at least the outer portions of planetary atmospheres (in which densities are low enough to permit satellite flight), the outer portion of the sun's atmosphere, and interplanetary space. It frequently also includes galactic space and intergalactic space. It is also frequently taken to

include planetary studies and the study of the earth's atmosphere at altitudes above those attainable by balloons. With such a broad coverage, there are many special areas of study included within the scope of space physics, and several of these are described separately; for example, see ASTROPHYSICS, COSMIC RAYS, IONOSPHERE, PLANETARY ATMOSPHERES, RADIATION BELTS, RADIO ASTRONOMY, and SOLAR PHYSICS.

Earth's Outer Atmosphere. The earth's atmosphere extends far out into space, something which would not necessarily be expected on the basis of atmospheric properties near the earth's surface. There are two factors involved in this great extension. First, above 100 km, the atmospheric temperature increases rapidly with altitude, causing an outward expansion of the atmosphere far beyond that which would have occurred had the temperature stayed within the bounds observed at the earth's surface. Second, above about 100 km, the atmosphere is sufficiently rarefied so that the different atmospheric constituents attain diffusive equilibrium distributions in the gravitational field; the lighter constituents then predominate at the higher altitudes and extend farther into space than would an atmosphere of more massive particles. This effect is enhanced by the dissociation of some molecular species into atoms. The pressure p at altitude h , in terms of the pressure p_0 at the earth's surface, is given by

$$p = p_0 \exp \left(- \int_0^h \frac{\bar{m}g}{kT} dh \right) \quad (1)$$

where \bar{m} is the average mass of the atmospheric particles, g is the acceleration of gravity, k is the Boltzmann constant, and T is the atmospheric temperature. It is clear from this expression that the high temperatures and low particle masses above 100-km altitude act to maintain pressures at still higher altitudes in excess of those that would exist if the temperature and molecular weight were constant with altitude. Where diffusion equilibrium prevails, Eq. (1) applies to each constituent separately, provided \bar{m} is replaced by the particle mass for the particular constituent under consideration and p_0 is the partial pressure at some reference altitude where h is taken to be equal to zero.

The composition of the atmosphere does not change much up to 100 km; there is a region of maximum concentration of ozone (still a very minor constituent) near 20 to 30 km (see PLANETARY ATMOSPHERES), the relative concentration of water vapor falls markedly from its average sea-level value up to 10 or 15 km, and the relative abundance of atomic oxygen begins to become appreciable on approaching 100 km, due to photodissociation of oxygen by ultraviolet sunlight. Above 100 km, atomic oxygen rapidly increases in importance, due to the combined influence of photodissociation and diffusive separation in the gravitational field; above 200 km, atomic oxygen is the principal atmospheric constituent for several hundred kilometers. However, helium is even lighter than atomic oxygen, so its concentration

falls less rapidly with altitude, and it finally replaces atomic oxygen as the principal atmospheric constituent above some altitude which varies with the sunspot cycle between 600 and 1500 km. At still higher altitudes, atomic hydrogen finally displaces helium as the principal constituent. The hydrogen extends many earth radii out into space and constitutes the telluric hydrogen corona, or geocorona.

The temperature of the upper atmosphere, and hence its density, varies with the intensity of solar ultraviolet radiation, and this in turn varies with the sunspot cycle and with solar activity in general. The solar radio-noise flux is a convenient index of solar activity, since it can be monitored at the earth's surface. The minimum nighttime temperature of the upper atmosphere above 300 km has been expressed in terms of the 27-day average of the solar radio-noise flux \bar{S} at 8-cm wavelength, as follows,¹

$$T = 280 + 4.6\bar{S}$$

This varies from about 600°K near the minimum of the sunspot cycle to about 1400°K near the maximum of the cycle. The maximum daytime temperature is about one-third larger than the nighttime minimum.

Magnetosphere. The magnetosphere is that region of space in which the geomagnetic field dominates the motion of charged particles. Near the surface of the earth, the geomagnetic field resembles that of a dipole; the best-fit dipole is off center about 440 km and is inclined about 11° to the earth's axis of rotation. Well out into space, the field is severely deformed so that it no longer resembles a dipole field. The most apparent deformation is that due to a plasma of charged particles flowing away from the sun, a flow generally referred to as the solar wind. When the kinetic energy of the directed flow of the solar wind exceeds the energy density of the geomagnetic field, the plasma displaces the field. The diamagnetic properties of the flowing plasma tend to compress and confine the geomagnetic field,² at least on the side facing the sun (there is conjecture that on the side away from the sun the geomagnetic field might be indefinitely extended). Calculations indicate that the surface of the magnetosphere facing the sun is roughly hemispherical, with dimples over the earth's magnetic poles. Observations by space probes indicate that the distance that the geomagnetic field extends towards the sun is about 10 earth radii.³

The magnetosphere is the region of space within which many geophysical phenomena are confined. The Van Allen radiation belt (see RADIATION BELTS) apparently extends out to the surface of the magnetosphere on the side facing the sun, although this is not so on the side away from the sun, where the magnetosphere has a tail extending at least as far as the moon's orbit and perhaps much farther. Any charged particles from the IONOSPHERE that have sufficient energy to escape from the earth's gravitational

field are constrained by the magnetic field to remain in the vicinity of the earth.

The solar plasma that compresses the geomagnetic field and limits the magnetosphere flows away from the sun at a velocity that might be described as hypersonic—the ordered velocity exceeds the average random thermal velocity of the particles. Although the medium is so rarefied that collisions are rare, the particles can interact with one another through the agency of magnetic fields contained within the plasma. As a result, a collisionless shock wave develops in the flow before it reaches the surface of the magnetosphere.⁴ Space probes have shown that the shock front lies about 4 earth radii beyond the surface of the magnetosphere in the direction of the sun.³

Auroras are luminosities in the upper atmosphere at high latitudes caused by energetic particles, mainly electrons, that flow from the outer magnetosphere into the atmosphere. The cause of this electron bombardment from the magnetosphere is a long-standing scientific mystery. There is an obvious relationship to solar activity, but the mechanism that relates these two phenomena remains unknown (see AURORA AND AIRGLOW).

Interplanetary Space. Up until about 1954, interplanetary space was thought to be essentially a good vacuum, devoid of interesting physical phenomena except for occasional sporadic events such as the ejection of gas clouds by the sun or the passage of comets. It is now recognized that interesting physical phenomena are always present. The solar corona expands continually, giving rise to a steady outstreaming into interplanetary space of ionized gas from the sun. As was mentioned above, this outflow of ionized gas is generally referred to as the solar wind.

The steady outflow of particulate matter from the sun was first recognized by Biermann in 1954 on the basis of the deflection of comet tails away from the sun—a deflection that was too great to be explained on the basis of light pressure. Biermann at first overestimated the strength of the outflow, because of an underestimate of the strength of the interaction between the solar plasma and the cometary plasma. The solar wind was first observed directly and measured with some accuracy in the spacecraft Mariner II. This showed that the concentration of solar material near the earth was of the order of 5 protons/cm³, along with a corresponding concentration of electrons, moving with a velocity of about 500 km/sec.⁷

Parker⁵ has given the most satisfactory explanation of the solar wind, describing it as a continuous hydrodynamic expansion of the solar corona, with a continuous heat input into the outflowing gas for a substantial distance near the sun. The flow can be compared to the flow of gas through a rocket nozzle, where, in the case of the sun, gravity plays the role in restricting the gas flow that the throat plays in the rocket nozzle. Parker has also shown that the outflowing, electrically conducting gas must pull the solar magnetic field out radially and

that the rotation of the sun must twist the radial pattern into a spiral. This provides a magnetic connection, or a guiding path, from the western portion of the sun to the earth for any cosmic radiation produced in solar flares, something that is confirmed by observation.

A surprising property of interplanetary space, as observed by space probes, is the irregularity of the magnetic field. Although the average orientation of the field agrees with the spiral pattern predicted by Parker, many irregularities are present.³ The magnetic field energy density is mainly due to the irregular fields, and it is approximately equal to the thermal energy of the solar wind particles, which is approximately 1 per cent of the energy of ordered flow. The real significance of these observations seems not to have been recognized at this writing.

A satisfying concept for the termination of the solar wind at some finite distance from the sun has been provided by Axford *et al.*¹ As the solar wind moves outward from the sun, its concentration falls according to an inverse square law, and the dynamic pressure that can be generated by stopping it falls accordingly. At some point, it must become so attenuated that its continued forward hypersonic flow will be stopped by the galactic magnetic field. At this point, there must be a shock front and a conversion of ordered energy of flow to disordered thermal energy. The heated gas beyond the shock front should cool mainly by charge exchange between the high-temperature protons from the solar wind and cool hydrogen atoms from galactic space. After charge exchange, the hydrogen atoms will carry the energy away. The cool proton gas left behind is less electrically conducting than was the hotter gas, and the magnetic field is gradually released from the proton gas, allowing the magnetic field lines to merge and the proton gas to drift out into galactic space.

The hydrogen atoms that are heated beyond the shock front have high enough velocities to penetrate far into the solar system, even to the vicinity of the earth's orbit, before becoming ionized by solar ultraviolet radiation. The hydrogen atoms within a few astronomical units from the sun scatter hydrogen Lyman-alpha radiation emitted by the sun, and this scattered radiation can be detected with instrumentation flown in rockets. The rocket observations can be used to determine the concentration of the high-velocity neutral hydrogen atoms in interplanetary space, and this in turn can be interpreted in terms of the distance from the sun to the shock front beyond which the hydrogen originates. Patterson *et al.*⁶ have shown that this interpretation indicates that the distance to the shock front is about 20 astronomical units (AU). The solar magnetic field spirals around about three times in this distance, and in the outer portion of the solar system, the magnetic field lines in the plane of the ecliptic are approximately circular, with the sun at the center.

Such a pattern of magnetic field in the solar system can be expected to produce significant

anisotropies in the cosmic radiation, whether of solar or galactic origin. This is most pronouncedly true when cosmic radiation is released from a point on the sun that is connected by a magnetic field line to the vicinity of the earth, in which case the cosmic radiation appears to approach the earth's magnetosphere from a point forty or fifty degrees to the west of the sun. A weak anisotropy is produced in the low-energy galactic cosmic radiation, and the anisotropy becomes smaller for the higher energy radiation.

SPECIFIC GRAVITY. See DENSITY AND SPECIFIC GRAVITY.

SPECTROSCOPY

Spectroscopy is the branch of science in which the interaction of energy between electromagnetic radiation and matter is investigated. It is one of the few branches of science which yield directly, accurate information concerning the nature of substances in their own environment; it has been until recently practically the only experimental method for obtaining extraterrestrial information. Its importance as a major experimental method in physics, chemistry, and the biological sciences, can be demonstrated by the wide range of problems which can be solved with its techniques.

FIG. 1. Schematic representation of the electromagnetic spectrum in which the spectral regions and types of transitions are shown.

The broad field of spectroscopy can be subdivided in various ways, e.g., according to the energy (or frequency) range of the electromagnetic radiation studied or according to the nature of the transition involved. Several processes which result in absorption or emission of energy may occur within an atom or molecule, but fortunately each process is associated with a fairly definite frequency range, with very little overlap. Figure 1 is a schematic representation of the electromagnetic spectrum in which the various regions and the type of transitions which occur in each are indicated.

At very high energies or high frequencies, the transitions involve changes in the atomic nucleus and are independent of the environment of the nucleus. At slightly lower energy, inner shell electronic transitions occur. Irradiation of a sample with x-rays results in expulsion of electrons from the inner shells and then emission of x-rays as the electrons return to their normal states (x-ray fluorescence). The frequency of the x-rays emitted is independent of the state of chemical binding and depends only on the atom.

Irradiation with still lower-energy photons results in electronic transitions in the valence shell. The frequency of the radiation emitted when outer-shell electrons, which have been

excited either thermally or by electric arc, return to their ground states depends on the element involved and is usually independent of chemical state. The x-ray fluorescence mentioned above and the emission spectra in the ultraviolet and visible regions are very useful in identification of elements present in a sample. Atomic emission spectra are also useful in determination of electronic energy levels in atoms and in determination of composition and other properties of stars, planets and comets.

With the exceptions of flame spectroscopy and the emission from upper atmospheres, molecules are not usually sufficiently stable at the high temperatures required for thermal excitation of outer-shell electrons and, therefore, do not emit radiation in far ultraviolet, ultraviolet and visible regions. However, molecules do *absorb* radiation in the far ultraviolet, ultraviolet, and occasionally in the visible regions, as a result of the excitation of outer shell electrons. The absorption spectra in these regions are useful in studying the electronic states of small or unsaturated molecules and in the analysis of unsaturated organic compounds and inorganic complex ions. The energy absorbed by the molecules is usually rapidly converted to vibrational, rotational, or translational energy, but occasionally emission occurs (fluorescence and phosphorescence).

In the infrared region, changes in vibrational energy, usually accompanied by changes in rotational energy, are observed as absorption spectra. (Vibrational emission spectra have only recently begun to be studied in detail.) At still lower frequencies, in the far infrared and microwave regions, pure rotational transitions are observed.

Radiation in the microwave and radio-frequency ranges is used for studying the very low-energy transitions which result from reorientations of nuclear and electron spins in an applied magnetic field, i.e., for nuclear and electron magnetic resonance studies.

The occurrence of an energy change depends on the ability of the molecule or atom to interact with the electromagnetic radiation. In general, energy is absorbed only if the energy of the incident radiation is precisely the same as the amount required for the transition to take place.

Certain other criteria must also be satisfied. For example, the criterion for the absorption or emission of vibrational energy by a molecule in the infrared region is that a change in the electric dipole moment of the vibrating species must occur during the vibration. That is, not only must the energy of the incident radiation equal the energy of the vibration, but also the vibration must produce a temporary displacement of the electrical center of gravity. For a pure rotational energy change, the molecule must possess a permanent electric dipole moment. Nor do transitions take place between all different energy levels. The number of transitions allowed is limited by selection rules which can be justified theoretically on the basis of the limitations which must be introduced in order to obtain acceptable solutions for the wave equations. For example, pure rotational energy changes are limited to transitions between adjacent levels.

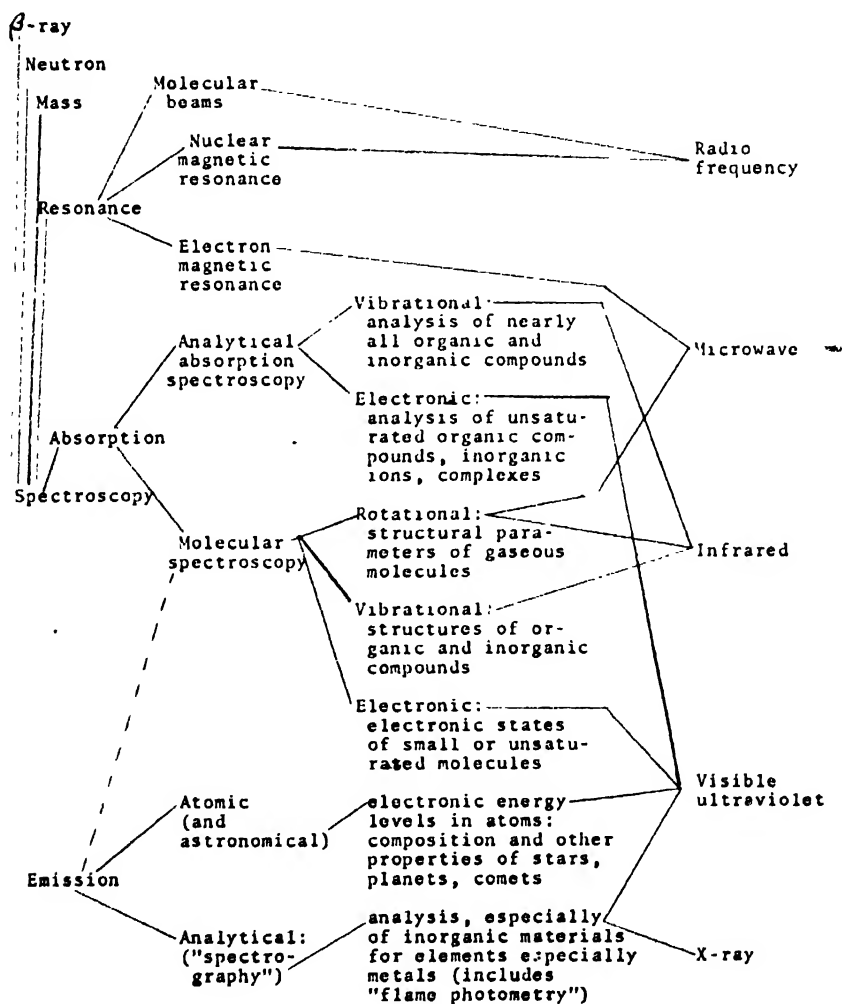

FIG. 2. Fields of spectroscopy (reproduced with permission from R. Bauman "Absorption Spectroscopy," New York, John Wiley & Sons, 1962).

The selection rules are occasionally defied, but the intensity of such a forbidden transition is usually low. Selection rules for linear molecules are fairly simple, but as the symmetry of the molecule decreases, the complexity of the selection rules increases.

Raman spectroscopy is an important exception to the rule that incident photons must possess exactly the correct amount of energy for the transition to occur. Under certain circumstances, frequencies in the visible or ultraviolet regions may be partially absorbed and cause the molecule to vibrate or rotate. The photon is then re-emitted with a new frequency, the Raman line, which is lower than the original and equal to the difference between the incident frequency and the vibrational frequency (see RAMAN EFFECT AND RAMAN SPECTROSCOPY).

The term "spectroscopy" has also been applied to some fields which do not involve electromagnetic radiation, but which use techniques similar to those of spectroscopy to separate a beam of particles according to their energy or other property. In β -ray spectroscopy, the energies of electrons emitted from nuclei are studied. In mass spectroscopy, charged particles are separated as a function of the ratio of charge

to mass. Figure 2 gives a summary of the fields of spectroscopy.

In order to indicate the broad scope of spectroscopy, some of the types of information which can be obtained and the experimental methods used to obtain them will be indicated. Studies in the ultraviolet, visible, infrared, microwave and radio-frequency regions have all found use in qualitative and quantitative analysis and in the determination of the geometry of simple molecules.

ATOMIC SPECTRA, which historically contributed extensively to the development of the theory of the structure of the atom and led to the discovery of the electron and nuclear spin, provide a method of measuring ionization potentials, a method for rapid and very sensitive qualitative analysis, a method for quantitative spectrochemical analysis, and data for the determination of the dissociation energy of a diatomic molecule. Information about the type of coupling of electron spin and orbital momenta in the atom can be obtained from the spectra obtained with an applied magnetic field. Other applications include the use of atomic spectra to obtain information about certain regions of interstellar space from the microwave frequency emission by hydrogen and the use of

FIG. 3. High-resolution vacuum-ultraviolet absorption spectrum of the E singlet $\pi \leftarrow X$ singlet Σ^+ transition in CO. (Courtesy of S. G. Tilford, J. Vanderslice, and P. Wilkinson, U.S. Naval Research Laboratories).

atomic spectra to examine discharges in thermonuclear reactions.

Molecular electronic spectra arise from changes in electronic energy accompanied by changes in vibrational and rotational energy. Were only the electronic energy changed during a transition, as in atomic spectra, a single line would be observed. Instead, for each electronic transition a system of bands is observed, each of which is composed of a group of lines. These lines result from the changes in rotational energy in each pair of the vibrational energy levels associated with the upper and lower electronic states (see Fig. 3) and BAND SPECTROSCOPY).

Data obtained from vibrational analysis of band systems of diatomic molecules and radicals can be used to determine the anharmonicity of the vibrational motion, approximate values for the dissociation energy of the species studied, and force constants of the upper and lower electronic states, to calculate the value of α in the Morse equation, and to assist in the statistical calculation of thermodynamic functions. Measurement of the relative intensities of adjacent rotational lines in a band of an electronic transition can lead to the determination of the nuclear spin quantum number.

Electronic transitions in polyatomic molecules have been classified according to the type of orbital occupied in the upper and lower electronic energy levels. The position of the band and its sensitivity to the degree of conjugation in the molecule can be used to distinguish between the possible types of transition and hence to elucidate the nature of the bonding involved. Knowledge of the effects of conjugation and substitution on electronic spectra of organic molecules leads to the use of electronic spectra in identification of characteristic groups. Study of electronic absorption spectra is valuable not only in qualitative and quantitative analysis, but also in the investigation of steric hindrance, isomerism, and intermolecular interactions such as charge-transfer phenomena.

In the infrared region, considerable work has centered on associating a particular frequency with a characteristic group or structural unit for application in qualitative analysis. Internuclear distances, bond angles, spectral moments of inertia, and force constants are some of the more fundamental quantities which can be determined by infrared and Raman spectroscopy. These methods have also been useful in statistical calculation of thermodynamic quantities, such as entropy and heat capacity. They have proved very valuable in quantitative analysis, especially in cases for which chemical analysis is difficult or inapplicable. Figure 4 shows the changes in the infrared spectrum of a mixture of ethyl esters of maleic and fumaric acids on fractional distillation. The Raman spectrum of allene showing rotational structure is given in Fig. 5.

Spectroscopy in the microwave region includes the study of pure rotational changes and electron spin resonance phenomena. In addition to its qualitative and quantitative applications, micro-

wave spectroscopy provides probably the most accurate method of determining internuclear distances of linear, symmetric top and simple asymmetric top molecules and bond angles for the last two types of molecules. (In some of these determinations, the use of isotopes is necessary.) It provides a method of evaluating the quadrupole coupling constant and gives values of electric dipole moments with accuracy equal to or better than that obtained by the best of the dielectric constant methods. Microwave studies have also been made on the potential energy barriers opposing rotation in liquid and solid samples (see MICROWAVE SPECTROSCOPY).

The microwave region is almost always chosen for electron spin resonance studies, but some work has been done at radio frequencies. Some of the principal applications of the electron spin resonance technique are the determination of nuclear spin quantum numbers, elucidation of electronic states of ions in the iron group transition elements, and determination of the spectroscopic splitting factor (all of which involve study of crystalline solids, investigation of delocalization of electrons in molecules and among radicals in solution), and chemical analysis and identification of unstable free radicals.

The variety of problems for which nuclear magnetic resonance spectroscopy is applicable is considerable. Nuclear magnetic moments, internuclear distances (between nuclei whose nuclear spin quantum numbers are not zero) in crystalline solids, some molecular geometry, and quadrupole coupling constants have been evaluated.

Internal motion with molecules has been detected by NMR methods and the energy barriers evaluated. By means of chemical shifts and electron-coupled nuclear spin-spin interaction, structural determinations can be made. Chemical exchange studies in which the exchanged atom has a nuclear magnetic moment can be followed by NMR methods. Quantitative and qualitative analytical applications arise from the examination of the number, spacing, position and intensity of the lines in the spectrum. Figure 6 shows the spin-spin splitting of the three resonance lines in a high-resolution NMR spectrum of ethyl alcohol.

The unusual power of spectroscopic methods in scientific research is perhaps best emphasized by the diversity of their application in other fields—from measurement of intermolecular interaction forces, observation and study of properties of unstable species which cannot be captured, determination of temperatures and composition of astronomical bodies, to study of microorganisms.

STARK EFFECTS. See ZEEMAN AND STARK EFFECTS.

STATES OF MATTER

In writing about the "states of matter" it would seem reasonable to begin by deciding

what is meant by "matter" and by "state." Let, then, a short space be devoted to those questions.

As for "matter" consider it this way. Consider a brazen sphere, cube, and pyramid. What have they in common? They are brazen, or "of bronze." Now let the sphere be brazen, the cube golden, the pyramid of iron. What have they now in common? They are all metallic, or "of metal." Now let the sphere be brazen, the cube wooden, and the pyramid of earthenware. What have they in common? They are all solid, or "of solid stuff." Finally, let the sphere be brazen, the cube water, the pyramid outlined with smoke in the air. What have they in common? They are all material, or "of matter." So matter is that which is common to all material objects, but is not involved with immaterial things—the binomial theorem, for instance, or the right-angled isosceles triangle is not, as an abstract idea, material. This argument shows us, moreover, that we never have any experience of matter in the abstract. It is always "this ingot of iron," "that block of stone," "the pile of clay over there." However, just as, while we never see "man" but always John Jones or Sam Smith or some such individual, it is convenient to talk about the abstraction "man"; even so, the abstraction "matter" can be a convenient one.

As for "states," suppose we think this way. What is it that, above all else, distinguishes material objects? Is it not that they are tangible? For, on the one hand, a rainbow is visible, but we should not call it "material"; on the other hand, if we had something invisible, but which we could feel, we should declare it to be "material." So tangibility, it would seem, is the criterion. Now as to tangibility we might divide objects into: (a) unyielding, (b) yielding but quite tangible, and (c) hardly tangible. And these three classes, of course, we call solid, liquid, and vapour or gas: the three states of matter in which we are interested. This argument shows why we

distinguish matter primarily into these classes, and not, for instance, according to color. It is because it is above all else tangibility in which we are interested.

It is true, of course, that the division into three classes will leave some doubtful cases at the borders, just as does the division of living things into animal and vegetable. And we can always deal with a thing according to the aspect which predominates in the circumstances in which we are interested, so that we might think of pitch, say, as a solid at one time, a liquid at another.

Gases. A gas, of course, must be kept in some container, and it tends to expand the container, unless prevented from outside. We say that it exerts pressure; for instance, the pressure of air near sea level is about 14.7 psi, or just over 1×10^6 dynes/cm². It is found that the pressure of a given amount (by weight) of a gas in a container depends on the volume of the container, and on the temperature. The relation may be a very complicated one, but at sufficiently low pressure and sufficiently high temperatures, it is approximately true for all gases that

$$\frac{PV}{T} = \text{Constant}$$

P represents the pressure of the gas, V the volume and T the temperature measured from absolute zero, which is at 273 C or 460 F, approximately. This kind of equation is called an equation of state, and this particular one is the law of ideal gases, and it is said that a gas behaving thus is an ideal gas. Actually, of course, there is no such thing as an ideal gas, but any gas under suitable conditions will behave nearly ideally.

Liquids. It is sometimes said that there is no simple equation for liquids corresponding to the ideal law for gases. However, it is close to the truth, under many circumstances, to write

$$V = \text{Constant}$$

i.e., the volume of the liquid is constant independently of pressure and temperature. In fact, this is not true; the liquid is compressed a little by pressure, and the volume usually increases a little with increasing temperature. Nevertheless, this simple law is probably as close to the truth as is the law of ideal gases in many of the circumstances in which it is used.

Solids. Likewise a simple law can be given for solids, i.e.,

$$L = \text{Constant}$$

L being the length of the line joining any two points in the solid. That is to say, not only does the volume not change, but neither is the solid distorted by any action on it. Again, this is only an approximation to the truth, and probably about as valid.

Changes of State. We often tend to think of a given kind of stuff as being in a particular state; for instance we think of water as liquid, iron as

solid, and air as gas. However we know that almost anything may exist in any of the states; water, for instance may be liquid, solid, or vapor. The ways in which things change from one state into another can be very interesting. (In books on THERMODYNAMICS, it may be mentioned here, in which these things are discussed in great detail, the word "phase" is often used instead of "state" as used here.) In general, the division between the different states depends on the pressure and temperature of the sample. Increasing the temperature makes the material go to a "looser" state; e.g., if ice is heated somewhat, it melts, and if the water is heated more, it evaporates. Increasing the pressure tends to squeeze the material into a "denser" state, either liquid or solid according to circumstances.

The way in which the state of a given material, say water, varies with pressure and temperature can be shown well in a graph such as that in Fig. 1. Every point on the graph will represent a certain combination of pressure and temperature, in the way of analytic geometry. The graph is divided into regions marked "solid," "liquid" and "vapor." At temperatures and pressures such as T_1 and P_1 , which give a point in the region marked "solid," the material is solid. Likewise at temperatures and pressures such as T_2 and P_2 , giving a point in the "liquid" region, the material is liquid. And at temperatures and pressures such as T_4 and P_4 , it is a vapor. Thus, this graph indicates the whole behavior of the material with respect to temperature and pressure. Note that the line dividing the "liquid" from the "vapor" region just ends at a point at temperature T_c and pressure P_c . These are called the "critical point," and the "critical temperature" and "critical pressure", respectively. At temperatures higher than critical, there is no distinction between liquid

FIG. 1. Phase diagram: Plot of pressure vs temperature for a typical material.

and vapor. For water, the critical temperature is 374°C ; critical pressure, 219 atmospheres.

It can be seen that three parts of the curve meet as it were, at the point given by T_3 and P_3 . This point is called the "triple point." For water, the triple point is at about 0.01°C and 4.6 mm of mercury. Note that if you warm a solid at pressures lower than the pressure at the triple point, it will change to vapor without first melting to a liquid at all. Such "dry evaporation" is called "sublimation." For carbon dioxide, for instance, the pressure at the triple point is about 5.1 times atmospheric. Thus, solid carbon dioxide, i.e., "dry ice," when allowed to warm up at atmospheric pressure, sublimates directly into vapor, as is well known. A process the reverse of sublimation happens when frost forms on cold objects without any intervening stage of liquid.

Vapor Pressure. In Fig. 1, along the curve joining the triple point and critical point, the "liquid" and "vapor" regions meet; i.e., liquid and vapor can exist together. Note, however, that at a given temperature, they exist together only at a certain pressure. This pressure is called the vapor pressure of the liquid at the temperature concerned.

An analogous thing could be said about liquid and solid, or solid and vapor, along the appropriate curves.

Vapor Pressure and Relative Humidity. In a certain volume, say one cubic foot, of air, there is, along with the air, ordinarily a small amount of water vapor. Suppose that this same amount of water vapor were put into a vessel of the same volume, i.e., one cubic foot, which contained nothing else at all. There would be a small pressure, perhaps about $1/50$ of atmospheric pressure. This pressure is called the partial pressure of the water vapor.

The ratio of the partial pressure of water vapor in the air to the vapor pressure of water at the temperature of the air is called the relative humidity. (There is a bit of approximation here, because water vapor is not really an ideal gas.) For instance, at 70°F the vapor pressure of water is about 20 mm of mercury. (Standard atmospheric pressure is 760 mm of mercury.) If the actual partial pressure of water vapor were 10 mm the relative humidity would be 0.5 or 50 per cent.

Changes of Volume and Shape of Liquids and Solids. The "equations of state" proposed above for liquids and solids are really too drastic; they ordinarily expand when heated. Typically, the volume of a liquid increases by 0.05 per cent for each degree Fahrenheit increase in temperature. (Water may be anomalous in this, as well as other respects.) They are compressed by the application of pressure; typically, the volume is decreased by 0.01 per cent for each atmosphere of pressure.

Solids are generally compressed only about $1/50$ as much as liquids by the same pressure. It is more interesting to know how much force is needed to stretch a bar of solid material. For

steel, it takes about 30,000 pounds force for each square inch of cross section of the bar to stretch it by 0.1 per cent. For other solids, the force needed is mostly less, typically one-third to one-tenth of that.

The Surface of Liquids. A liquid, if it does not fill the container entirely, has an exposed surface. If an attempt is made to stretch the surface, for instance by withdrawing a horizontal piece of wire from the liquid, the surface acts as if it were an elastic sheet. The force necessary to stretch a unit length of surface is called the **SURFACE TENSION**. For instance, the surface tension of pure water around room temperature is about 72 dynes/cm. The addition of impurities, e.g., soap to water, reduces the surface tension greatly. The rising of liquids in fine tubes or in porous materials is connected with surface tension.

Molecular Theory of the States of Matter. The molecular theory considers all matter to be built up of molecules in some arrangement (or lack thereof!), each molecule, in turn, consisting of one or more atoms. The molecules attract one another with forces of electrical origin, and thus may stick together. However, they are also in motion or at least vibration, and this tends to make them break apart. The motion increases with increasing temperature, hence the structure "loosens." In a gas, around atmospheric pressure and room temperature, the molecules are about 3×10^{-7} cm apart; the forces between them are very small and they move almost freely and randomly. In so doing, they bombard the walls of the vessel; the effect of this bombardment is the pressure.

In a liquid or solid, the molecules are typically only about one-tenth as far apart. The forces then hold the molecules together; their motion is reduced to a vibration which never gets them far from one place. Occasionally, one molecule gets an extra hard push and flies away; this is evaporation or sublimation. According to the nature of the molecules, they may pile together as would a heap of spheres, or they may stick together in chains or other arrangements.

In a liquid the distance between molecules is about the same as in a solid. The different behavior may be because of a few "holes" in the liquid, i.e., places, a few per cent in all, where a molecule is missing. These spaces allow the liquid to flow, just as on a checker board when a few of the men are missing, the whole pattern can be moved by shifting men into and out of the holes. Of course this takes time, and it shows up in the viscosity or "slowness" of liquids. Molasses, for instance, is very viscous, water not very.

Various Kinds of Solids. In solids as was mentioned above, the molecules may be packed, arranged in chains, etc. Corresponding to these are the classes: metals, polymers, etc. Sometimes these are all spoken of as different states of matter, but from the present viewpoint it seems better to call them special kinds of solid.

STATIC ELECTRICITY

Until it was accepted that galvanic currents are identical with moving electric charges, *static electricity* referred to all electric charge that was stationary or nearly so, including for example, that on Leyden jars and pyroelectric crystals. Nowadays the meaning is restricted to the more or less immobilized charge resulting from (1) redistribution of charge on a single body through *induction* by the charge on neighboring bodies; or (2) transfer of charge from one material to another by *contact* and subsequent separation. Sometimes the term is widened to cover the charge transferred through the action of external fields, as with electrostatic generators wherein charge is sprayed onto a conveyor by corona discharge; sometimes it is not, as with photoelectrets. The redistribution of charge by temperature gradients as with pyroelectrics and thermoelectrets, is generally excluded.

In scientific and technical work, it is often important to control static electricity, either to exploit its effects or to avoid them. For convenience we divide the problem into (a) generation of charge and (b) dissipation of charge. So far as generation is concerned, induced electrification is largely understandable in terms of classical physics; the fundamentals are well understood, and the applications are straightforwardly made as part of electrical engineering and safety engineering (see ELECTRICITY). Contact electrification, on the other hand, is far from being understood, and immediately comes to frontier problems in the modern theory of liquids and solids. So far as dissipation is concerned, the origin of the charge is largely irrelevant; a wide variety of physical and chemical processes of all degrees of complexity enter in analyzing the decay or neutralization of static charge.

Generation. Induction phenomena, as mentioned, are adequately described as a branch of classical electrostatics. Hence we limit our discussion here to the more poorly understood topic of contact phenomena. When two materials

differing at their surfaces in chemical composition, or even temperature or state of strain, are placed in contact, charge tends to flow from one to the other until their electrochemical potentials are identical. If the materials are subsequently separated, some portion of the transferred charge is retained, the potential difference between the materials increasing as the capacitance decreases. As a rule, this net transfer produces no noteworthy effects; in fact, a sensitive electrometer is ordinarily needed to measure it. With metal-metal contacts, the charge retained is invariably very small and is not detected by the senses. With metal-insulator or insulator-insulator contacts, the charge transferred while the materials remain in contact may be large, but it decreases during separation to an unimportant amount unless the insulator has quite high resistivity. At the speeds encountered in ordinary events, say about 100 cm/sec, the charge leaks back too fast to give noticeable effects whenever the resistivity of the more poorly conducting material falls below about 10^9 ohm-cm. At higher speeds, static effects become noticeable even at low resistivity, whereas at lower speeds they appear at very high resistivity.

The combination of moderate or high speed and high resistivity frequently produces large enough charge transfer that the surrounding medium breaks down electrically. In air at atmospheric pressure, the requisite charge densities on a uniformly charged plane conducting surface are about 8 esu (statcoulombs/cm²) or 2500 $\mu\text{C cm}^2$, to give a field of about 30 kV/cm just above the surface. This density represents about $2 \cdot 10^{10}$ electronic charges per square centimeter, so that only one in perhaps 10^9 surface atoms is charged even at the highest electrifications ordinarily occurring.

For practical purposes, the phenomena of interest in static electrification are the forces of attraction or repulsion resulting from excess charge (e.g., in textile processing, ore separating, and electrostatic copying), the occurrence of sparks and their consequences (e.g., in transfer of flammable liquids, or in processing of photographic films), and so on. From a fundamental point of view, these phenomena are simply consequences of transfer of charge and its subsequent behavior. Hence we may take as the central question in static electrification the following: Given two materials of specified chemical composition and physical state, what is the charge—in sign and amount—transferred when they are placed in contact under specified mechanical and ambient conditions, and then separated?

At the present stage of theory of matter, an answer is available only for some very special situations. For the rest of the cases, we must content ourselves with trying to get some guidance from crude models of the type to be described below. For brevity let us restrict our considerations to solid-solid contacts, even though liquid-solid contacts are almost as important technologically. Furthermore let us as a rule consider bodies that are uncharged before contact. We

assume first that a certain charge q_0 is transferred between two objects while they are touching. For many materials, q_0 will increase with duration of contact towards an equilibrium value q_∞ . We designate as α the degree of attainment of this value, writing $q_0 = \alpha q_\infty$. We should expect q_∞ to depend on the chemical nature of the materials, as well as on the mechanical nature of the contact, i.e., on the size and shape of the objects, and the normal force between them. Let us write q_∞ as a factor b ("b" for band structure, in the case of solids) dependent on the electrochemical properties of the materials, multiplied by a factor g ("g" for geometry) dependent on the mechanical parameters of the contact. Upon separation some of the charge returns to its origin, or is otherwise lost from the object; let us call f that fraction of the initial charge q_0 that remains to give the observed charge $q = q_0 f$. Upon combining all these relations, we get a four-factor formula

$$q = \alpha b g f$$

The utility of this expression can be assessed only by experience. Note that α and f are both positive numbers between zero and unity, and that g is intrinsically positive; the sign of the charge enters in b .

An important qualitative consequence of the above scheme is the existence of a *triboelectric series*, i.e., a listing of materials such that any one in it becomes positive when rubbed against another lower in the series. When the materials, the ambient conditions, and the mode of contact are reasonably well defined, such series are generally conceded to exist. An example is the following: Wool, nylon, viscose rayon (regenerated cellulose), cotton, silk, cellulose acetate, polymethylmethacrylate, polyvinylalcohol, polyethylene, polytetrafluoroethylene. In principle, one ought to be able to predict the position of a given substance from its chemical properties, but as yet the attempts have been more suggestive than successful.

So far as quantitative results are concerned, prediction of α and b is possible in principle when detailed information is available on the energy levels of the materials. As yet, only metal-metal systems have been found to be simple enough to be analyzed successfully. With insulators, surface state of high complexity may occur.

Prediction of g is hopefully made by estimating the area of "true contact," namely, the area where atomic fields interpenetrate. The effective width of this area should be proportional to some fractional power of the normal force, not less than $1/3$ and in some geometries approaching unity. The effective length of this area should again be proportional to a fractional power of the normal force in the case of stationary contact, but independent of normal force and proportional to the length of stroke in the case of sliding or rolling contact. Experiment tends to confirm these relations when the charge is not limited by atmospheric breakdown. In such cases a saturation value of charge is reached, its magnitude dependent on the atmospheric pressure.

Prediction of f is made by analyzing the time scale of the experiment. We expect f to be a function of the ratio of T , a time characteristic of the speed of separation, to τ , a relaxation time characteristic of the material of higher resistivity. The separation time T may be taken as l_0/v , where v is a speed of separation, and l_0 is some characteristic length; the relaxation time τ should be related to the time constant for redistribution of charge in a medium of dielectric constant ϵ and volume resistivity ρ . We have then $T/\tau = (l_0/v)/(\epsilon\rho)$, and we see that velocity may be traded for resistivity, since $f = f(T/\tau) = f(l_0/\epsilon\rho v)$. For ordinary materials at ordinary speeds, f is very small for ρ lower than 10^9 ohm-cm. For metal-metal contacts in particular, where $\rho \sim 10^{-5}$ ohm-cm, static effects disappear, their only remnant being the slight transfer due to contact potential difference.

Dissipation. Charge may be dissipated by currents within the body of the object or over its surface, or by currents within the medium in which the object is immersed. Charge in the interior of a body ultimately reaches the boundaries, decaying exponentially with a well-defined time constant $\epsilon\rho$. Charge on the surface of a body moves to attain an equilibrium distribution, decaying in a complicated fashion that is only approximately described by a time constant proportional to $\epsilon\rho$. Currents within the medium surrounding the object are described by the laws of electrical conduction in liquids or gases, as the case may be, in all their complexity.

Control of Static Electrification. Effects of static charge, beneficial or harmful, can be controlled by influencing either the production of charge or its neutralization.

Production of Charge. In the case of induced electrification, the fields between objects may be controlled by altering the potentials of neighboring conductors, usually by screening and grounding. In the case of contact electrification, the four-factor formula may be used as a basis for discussion:

CONTROL OF α : The only practical control is through fixing of the charge state of the object. (We must accordingly generalize our analysis to include objects initially charged.) If one object has lost so much charge that it can lose no more upon contact with another object, this second object will remain in its initial charge state. (As an illustration, a yarn running through an insulating or insulated guide may not pick up more charge after a brief initial period in which the guide electrically "saturates.")

CONTROL OF b : In principle, the electrochemical potential for one given material may be matched against that for some other material so that charge transfer between the two is negligible; in practice the potentials cannot be controlled closely enough, particularly over a range of ambient and mechanical conditions. More significantly objects usually must work against a variety of materials which will have a variety of electrochemical potentials. There have been proposed composite surfaces wherein a material

high in the triboelectric series is interspersed with one low in the series to give a small average electrification. The efficacy of such blending is high in some applications.

CONTROL OF g : Decrease of the normal force almost always produces a decrease in charge transfer. In cases where the dependence follows a fractional power law, it may not be useful to go to great lengths to decrease the normal force to very small values. With respect to path length, action is obvious though seldom practical.

CONTROL OF f : In practice, charge transfer is reduced by decreasing the product $\epsilon\rho v$. It is difficult to alter the dielectric constant by more than a small factor and hence to affect the rate of dissipation strongly in this way. The resistivity, on the contrary, may be changed greatly, either by changing the molecular structures of the body (say by grafting conducting segments onto polymers) or by adding conducting materials to the surface of the object (say by adding moisture or various antistatic agents). With hydrophilic materials, one traditionally alters the moisture content of the surrounding air, with that of the object following. The resistivity varies as a high negative power of the moisture content, and a change in relative humidity of a few per cent may bring about a tenfold difference in charge observed at a given time, or a tenfold difference in the time required to attain a given charge state. In a few special applications, the resistivity may be lowered by increasing the temperature. The factor r can be decreased by simply slowing down the process, of course, and also by changing the mode of contact, say from sliding to rolling (with concomitant change in g), or by lowering the relative speed of the two contacting objects.

Neutralization of Charge. Surplus charge inexorably is neutralized, since the resistivities of even the best nongaseous insulators seldom exceed 10^{18} ohm cm or so, and since natural radioactivity and cosmic rays produce mobile ions in surrounding fluids. When it is desired to hasten neutralization, charge must be supplied by other means. The conductivity of the body can be increased, especially at the surface, according to some of the ideas expressed earlier. More commonly, charge can be supplied through the surroundings. The medium in which the object is immersed can sometimes be rendered conductive by the electric field set up by the body itself, especially at surface regions of small radius of curvature, for example, at the points of tinsel or needles. Although the charge cannot be completely eliminated in this way, it can be made quite small if the ambient pressure can be brought near the minimum in the Paschen law for electrical breakdown in gases.

More often the surrounding atmosphere is ionized with the aid of external agents. Various commercial static eliminators have been developed to produce glow or spark discharges from high-tension wires or points. Electromagnetic radiation, in the form of x-rays or gamma rays, will ionize surrounding media, but it is often objectionable because of its hazards to personnel.

Particle radiation, in the form of alpha or beta rays, is very effective in producing ions, and is easier to control with respect to health hazard. Plutonium 240 with a half-life of 6600 years and americium 241 with a shorter half-life of 462 years are alpha emitters nearly free from gamma rays. They are modern substitutes for the nearly gamma-free polonium 210 with half-life of 138 days, and the gamma-active radium 226 with half-life of 1620 years. Flames produce copious ionization, but their action is usually only ancillary, as in flame-driers at the take-off of some printing presses.

STATICS

Statics is the branch of MECHANICS which studies the conditions of equilibrium of forces acting on particles or rigid bodies, or on inextensible cords, belts and chains. HYDROSTATICS, the study of the equilibrium of fluids, is usually not regarded as a part of statics in the conventional sense of the term.

Statics is the oldest branch of mechanics, some of its principles having been used by the ancient Egyptians and Babylonians in their constructions of temples and pyramids. As a science it was established by Archytas of Taras (ca. 380 B.C.) and primarily by Archimedes (287–212 B.C.); it was further developed by medieval writers on the "science of weights" such as Jordanus de Nemore (thirteenth century) and Blasius of Parma (fourteenth century). In the sixteenth century, it was revived by Leonardo da Vinci, Guido Ubaldo and especially by Simon Stevin (1548–1620) who laid the foundations of modern statics (inclined plane, equilibrium of pulleys, parallelogram of forces).

Although the laws of statics can in principle be derived from those of dynamics as a limiting case for vanishing velocities or accelerations, statics has been developed, since the end of the eighteenth century, independently of dynamics. Its fundamental notion, like that of dynamics, is the concept of *force*, representing the action of one body on another and characterized by its point of application, its magnitude and its direction (line

of action) or briefly by a VECTOR \mathbf{f} . Two equal and opposite forces whose lines of action are parallel and non-coinciding are said to form a *couple*. The *moment* or *torque* \mathbf{m}_O of a force \mathbf{f} about a point O is a vector whose magnitude is the product of the magnitude of \mathbf{f} and the length of the perpendicular distance of O from the line of action of \mathbf{f} , or in VECTOR notation $\mathbf{m}_O = \mathbf{r} \times \mathbf{f}$ (vector product), where \mathbf{r} denotes the vector from O to the point of application of \mathbf{f} .

The following four principles may serve as the basic postulates for statics. (1) *The principle of composition (addition) of forces*: two forces, \mathbf{f}_1 and \mathbf{f}_2 , with a common point of application A can be replaced by a third force, the resultant \mathbf{f} , which is obtained graphically (geometrically) as the diagonal, from A , in the parallelogram determined by the two given forces, or analytically (algebraically) as the vector whose components, usually with reference to a rectangular reference system, are the sum of the corresponding components of the two given forces, $f_x = f_{1x} + f_{2x}$, etc. (vector addition). The resultant of more than two forces is independent of the order of addition. (2) *The principle of transmissibility of force*: the point of application of a force acting on a rigid body can be transferred to any other point on the line of action of the force provided the point is rigidly connected with the body (sliding vector). (3) *The principle of equilibrium*: the necessary and sufficient condition for the EQUILIBRIUM, that is, absence of accelerated motion, of a particle is the vanishing of the resultant of all forces acting on the particle, or $\mathbf{F} = \sum \mathbf{f}_i = 0$. The condition for the equilibrium of a rigid body is the vanishing of the resultant of all forces as well as the vanishing of the resultant of their moments about an arbitrary point O , or $\mathbf{M}_O = \sum (\mathbf{r}_i \times \mathbf{f}_i) = 0$. If $\mathbf{F} = 0$, \mathbf{M}_O is independent of the choice of O . (4) *The principle of action and reaction* (Newton's third law): the force exerted by one body on another is equal and opposite to that exerted by the second body on the first and both forces lie along the same line of action.

These principles imply the following results. Two parallel forces can be added if additional compensating forces are introduced. Any set of coplanar forces, with the exception of couples, can be reduced to a single resultant. The sum of the moments of any two intersecting forces about any point in their plane equals the moment of their resultant about the same point (Varignon's Theorem). Any system of forces acting on a rigid body can be reduced, in an infinite number of ways, to a single resultant \mathbf{F} and a single couple \mathbf{M} . In all these reductions \mathbf{F} is uniquely determined but \mathbf{M} depends on the position of \mathbf{F} . There is one, and only one, line of action for \mathbf{F} , called *Poinsot's central axis of the system*, for which \mathbf{M} is parallel to \mathbf{F} . Hence every system of forces is equivalent to a *wrench* as this particular force-couple combination is called.

Statical analysis of framed structures or trusses, collections of straight members pinned or jointed together at the ends, is based on the preceding theorems. Such structures rest upon supports

whose reactions or pressures have usually to be determined in practical applications. The equilibrium conditions, according to (3), are two vector equations or, equivalently, six scalar equations and hence can be solved for no more than six unknowns (the reactions at supports and connections). If the reactions involve more than six unknowns, some of the reactions are statically indeterminate; if less, the body is said to be unstable. In case the unknown reactions arise from constraints, i.e., conditions restricting possible motions, a convenient method for the elimination of unknown reactions is the use of the *principle of virtual work* according to which the total virtual work (work due to a possible small displacement which need not necessarily take place) of the external forces acting on the body vanishes for any virtual displacement of the body. In general, internal forces, holding together the various parts of the structure, also have to be taken into account, e.g., for trusses which consist of straight members connected by joints.

In particular, parallel forces can always be replaced by a single resultant whose point of application is called the *center of the system of parallel forces*; it is invariant if all forces change their directions but remain parallel to each other. In this case the sum of the moments of these forces about any point equals the moment of their resultant about the same point; in particular, the sum of the moments about any point on the resultant is zero (generalization of the law of the lever). An important case of this kind is that of the earth's gravitational forces which act at a given place in practically parallel lines on every element of a not too voluminous body. The center of the system of forces, in this case, is the *center of gravity* and is identical with the center of mass or *centroid* which can easily be determined by summation for a system of discrete particles or by integration for continuous masses.

The study of friction, the resistance of a surface to the motion of a body upon it, belongs properly to applied mechanics. Since however many problems in statics involve, at least, considerations concerning *static friction* (the frictional force which just prevents motion), the study of FRICTION is often included in the science of statics.

MAX JAMMER

STATISTICAL MECHANICS

The object of statistical mechanics is the explanation of the macroscopical physical phenomena as consequences of the laws of motion of the atoms and molecules. Equivalently, statistical mechanics can be defined as the mechanics of systems of a very large number of degrees of freedom. Whereas in "ordinary" mechanics even the three-body problem cannot be solved exactly, statistical mechanics takes advantage of the large number N of degrees of freedom and tries to formulate exact *asymptotic* results in the limit $N \rightarrow \infty$ (in a certain well-defined way).

The fundamental laws of motion of the atoms and molecules are those of quantum mechanics; however, in many statistical mechanical problems, classical mechanics provides a sufficient approximation.

In ordinary classical mechanics, a problem is completely specified when the initial positions and momenta of all its particles are specified. Such information is impossible to obtain, and moreover is completely useless, for systems consisting of about 10^{24} particles. The only initial data which are interesting for such systems are of a macroscopic nature: density, local velocity, temperature at each point of a fluid, correlations between the density fluctuations in two points of the system, etc. There is a very large number of microscopic initial configurations of the molecules which is compatible with a given macroscopic specification. Hence, in order to describe such systems, Gibbs introduced the concept of an *ensemble*. This is defined as a set of a very large number of systems, all dynamically identical with the system under consideration (i.e., having the same hamiltonian H), differing in the initial conditions of the molecules but compatible with the macroscopic specification of the system.

The natural mathematical framework of such a description is the *phase space*, a many-dimensional space whose coordinates are the positions x_1, \dots, x_N (shortly: x) and the momenta p_1, \dots, p_N (shortly: p) of all the particles of the system. A point in phase space therefore represents a complete dynamical system in a definite microscopic configuration. A Gibbs ensemble corresponds to a cloud of points in phase space, which can usually be considered as a continuous distribution. The basic concept is therefore the *distribution function* in phase space $\rho(x, p; t)$, giving the density of the ensemble as a function of the positions and momenta of the particles (i.e., of the coordinates of the phase space) at time t . The connection between microscopic and macroscopic physics is then given by the following assumption: The observable value of a dynamical property of the system, (e.g., density, local velocity, average energy, etc.), $\bar{A}(t)$, is the average value of the corresponding microscopic dynamical function $A(x, p)$, weighted by the distribution function:

$$\bar{A}(t) = \int dx \int dp A(x, p) \rho(x, p; t) \quad (1)$$

Practically all functions $A(x, p)$ of physical interest are sums of functions involving only one or two particles. Hence it follows from Eq. (1) that the functions of real importance are the integrals of $\rho(x, p; t)$ over all but one or two particles: these are called reduced (one- or two-body) distribution functions. Their main importance comes from the fact that they remain finite in the limit $N \rightarrow \infty$.

The evolution of the system in time is described by the change in time of the distribution function. According to the laws of classical mechanics, the latter obeys a partial differential equation called the *Liouville equation*:

$$\frac{\partial \rho}{\partial t} + \sum_{i=1}^N \left[\frac{\partial H}{\partial p_i} \frac{\partial \rho}{\partial x_i} - \frac{\partial H}{\partial x_i} \frac{\partial \rho}{\partial p_i} \right] \equiv \frac{\partial \rho}{\partial t} + [\rho, H] = 0 \quad (2)$$

The bracketted expression $[\rho, H]$ is called the Poisson bracket of the hamiltonian H and the distribution function. The purpose of classical statistical mechanics is the solution of the Liouville equation in the limit $N \rightarrow \infty$.

In quantum statistical mechanics, the conceptual situation is much the same, but it is more complicated because of the proper statistical character of the quantum description of even a single system. Indeed, due to the HEISENBERG UNCERTAINTY PRINCIPLE, the momentum and the position of a particle can never be measured simultaneously with arbitrary accuracy. Hence the concept of a phase space has no meaning in quantum mechanics. The maximum information which can be obtained about a single system (in a "pure" state) is contained in its wave function $\Psi(x; t)$. The observable value of a dynamical variable in such a state is given in terms of the corresponding operator \hat{A} by the expression

$$\bar{A}(t) = \int dx \Psi^*(x; t) \hat{A} \Psi(x, t) \quad (3)$$

To this statistical aspect of quantum mechanics is added the proper indeterminism of statistical mechanics. Suppose the wave function of a single system (n) can be expanded in a series of orthonormal functions $\varphi_i(x)$ [see WAVE MECHANICS]

$$\Psi^{(n)}(x; t) = \sum_i a_i^{(n)}(t) \varphi_i(x) \quad (4)$$

In the statistical mechanical description, the single system is replaced by an ensemble, in which each system (n) is weighted by a density p_n . The role of the classical distribution function is now played by the *density operator* ρ introduced by J. von Neumann (1932). The matrix elements of this operator in the present representation are defined by

$$\rho_{ij} = \sum_n p_n c_j^{(n)} c_i^{(n)*} \quad (5)$$

the sum over n running over all the systems of the ensemble.

The averaging prescription which replaces Eqs. (1) and (3) is now:

$$\bar{A}(t) = \text{Trace } \rho \hat{A} \quad (6)$$

It is easily seen that this rule embodies the double averaging necessary for quantum and statistical mechanics. The evolution in time of the density operator is given by von Neumann's equation:

$$\frac{\partial \rho}{\partial t} + \frac{1}{i\hbar} [\rho H - H \rho] \equiv \frac{\partial \rho}{\partial t} + \frac{1}{i\hbar} [\rho, H] = 0 \quad (7)$$

H again being the (quantum) hamiltonian of the system. The classical Poisson bracket has been replaced by $(i\hbar)^{-1}$ times the commutator of the operators ρ and H .

Quantum statistical mechanics shares with the usual quantum mechanical many-body problem the following characteristic feature [see WAVE MECHANICS]. It is known that in a system of several identical particles, the latter are indistinguishable. In order to satisfy this requirement, the wave function of the system must be either symmetrical or antisymmetrical with respect to a permutation of any two particles. This symmetry requirement introduces the classification of quantum statistical systems into systems of *bosons* (Bose-Einstein statistics, symmetric wave functions) and systems of *fermions* (Fermi-Dirac statistics, antisymmetric wave functions). The purpose of quantum statistical mechanics is the solution of Eq. (7) with the proper symmetry condition.

The simplest solutions of Eqs. (2) or (7) are the time-independent solutions: these are functions of the hamiltonian H alone. They describe systems in equilibrium. A particular function of the hamiltonian is the *canonical distribution*:

$$\rho = Ce^{-H/kT} \quad (8)$$

where C is a normalization constant and k is called the Boltzmann constant. It can be shown that this distribution represents a system in thermodynamical equilibrium at temperature T . The main result in classical equilibrium statistical mechanics is the following: Consider the function

$$Z(V, T) = (N! h^{3N})^{-1} \int dp \int dx e^{-H(p, x)/kT} \quad (9)$$

the integration extending over the whole volume occupied by the system in phase space. $Z(V, T)$, as a function of the volume and of the temperature T , is called the *partition function*. It can be shown that the Helmholtz free energy $F(V, T)$ of the system [see THERMODYNAMICS] is given by

$$F(V, T) = -kT \ln Z(V, T) \quad (10)$$

The importance of this formula lies in the fact that the knowledge of a thermodynamic potential such as $F(V, T)$ enables one to calculate all thermodynamic properties (pressure, entropy, specific heat, etc.) by simple differential operations. A completely analogous result holds in quantum statistical mechanics.

Although the basic problem of equilibrium statistical mechanics is solved in principle (i.e., it is reduced to quadratures), the explicit evaluation of the $6N$ -fold integral occurring in the partition function poses a formidable mathematical problem. Only in the case of systems of noninteracting degrees of freedom can one calculate the partition function exactly. Moreover, essentially three main groups of systems of interacting particles are thoroughly understood at the present time. All of these systems are characterized by the following hamiltonian:

$$H = H_0 + \lambda V \quad (11)$$

where H_0 is the hamiltonian of a set of independent particles, whereas V describes the interactions and λ characterizes the size of the interactions. The three cases mentioned are the following:

(a) *Weakly coupled gases*. These are systems in which the interparticle interactions are weak; the partition function can then be expanded in a power series in λ .

(b) *Dilute gases*. In real gases, the particles interact through forces which have a very short range (the molecules can usually be idealized as hard spheres). In a dilute gas the molecules move most of the time in straight lines and occasionally suffer collisions, which are more and more frequent and involve more and more particles simultaneously as the density of the gas increases. H. D. Ursell (1927) and J. E. Mayer (1937) have shown that the partition function, and hence the pressure, can be expanded as a power series in the density; the result is the famous *virial equation of state* (or *cluster expansion*). The original derivation of this equation made extensive use of a diagram technique, a procedure which establishes a one-to-one correspondence between certain mathematical expressions and certain graphs; such diagram techniques proved to be of major importance in modern perturbation theory. The coefficients of the various powers of the density (or virial coefficients) are expressed in terms of so-called cluster integrals, describing correlations of various types between a given number of particles (see KINETIC THEORY).

The cluster expansion breaks down as the density increases and reaches the critical point. The condensation phenomena and the LIQUID STATE are not yet clearly understood.

(c) *Plasmas*. The ionized gases, or plasmas, have a radically different behavior as compared to "usual" gases. This is due to the long range of the Coulomb forces. As a result, one cannot speak of collisions in the ordinary sense: the interactions have a markedly collective character, involving many particles simultaneously. Mathematically, the various virial coefficients turn out to be divergent. J. E. Mayer (1950) has shown that by rearranging the cluster expansion and by performing summations of certain subseries, one can obtain a convergent equation of state for a plasma, the first term of which agrees with the one calculated by Debye and Hückel in their famous theory of electrolytes (which is semi-phenomenological) (see PLASMAS).

Whereas equilibrium statistical mechanics is in a state where the difficulties are mainly mathematical, nonequilibrium statistical mechanics is still in a state where the principles and the ideas are not yet completely clarified and unified. Most of our present knowledge has been achieved in the last twenty years, and this field is still in rapid growth.

The main problem here is to understand the basic paradox of irreversibility: whereas the laws of mechanics are invariant with respect to an inversion of time, the macroscopic evolution (e.g., heat conduction, dissipative phenomena, etc.) is irreversible. In older theories (Boltzmann), it was argued that due to the large number of particles and their complicated motions, one could invoke a probabilistic argument which, superposed to mechanics, yields readily an explanation of irreversibility.

There exist at present a few formalisms for the treatment of nonequilibrium mechanics (they are all equivalent). The basic idea in the modern theories is to avoid the probability arguments. Irreversibility appears as a property of the solutions of the mechanical equations, for systems of many particles and over sufficiently long times. More exactly, it can be shown that the Liouville equation reduces, for large systems, to a rather different equation, called the *master equation*. The latter describes a behavior which has a mixed character of reversibility and of irreversibility. In the three limiting cases mentioned above (weak coupling limit, dilute gas limit, plasma limit), there appear two natural time scales: the duration of a collision and the time between two collisions. The latter is much longer than the former. It can then be shown that for times much longer than the short time scale, the *reduced* distribution functions evolve practically independently of the rest of the correlations. They obey *kinetic equations* which describe an irreversible approach to equilibrium. In most cases other than the three limits described, the two time scales are no longer widely separated, and the evolution is much more complex.

One of the practical purposes of nonequilibrium statistical mechanics is the calculation of transport coefficients (thermal and electrical conductivity, viscosity, etc.) from molecular data. This can be done by starting from the kinetic equations. Alternatively, it has been shown recently (M. S. Green, R. Kubo) that a compact expression for most transport coefficients can be obtained from general arguments. The "Kubo formulas" express these coefficients in terms of an autocorrelation function of two microscopic currents (electrical currents, heat flow, etc.) averaged over the equilibrium distribution function. These two equivalent approaches can be combined in order to form a basis for the rigorous calculation of transport coefficients (see TRANSPORT THEORY).

Many other important results have been obtained recently in statistical mechanics; they cannot be reviewed in such a short article. The interested reader is referred to the existing textbooks, such as those given below.

STRONG INTERACTIONS

Only two types of fundamental interaction operate in classical physics, which account for all macroscopic and chemical phenomena including atomic structure. There are the gravitational forces which control the motion of bulk matter, which is electrically neutral—particularly the motion of the planets in the solar system. Then there are the electromagnetic forces which govern the motion of the electrons in atoms, and also give rise to the interactions between atoms and, hence, form the basis of all chemical reactions.

An atom has a radius of about 10^{-8} cm. In an atom, a cloud of electrons orbit about a central nucleus with a radius of about 10^{-12} cm. These nuclei are made up of nucleons—protons and neutrons. The total charge, which is determined by the number of protons, fixes the chemical nature of the atom. The nuclei are extremely stable, remaining unchanged through the most violent chemical reactions. The gravitational forces within a nucleus are completely negligible compared with the electrical repulsion between the charges on the tightly packed protons. Since the electrical forces tend to blow the nucleus apart, it follows that a completely new, specifically nuclear, force must be operating to form these stable structures. This force is of short range, only effective when the nucleons are less than 10^{-12} cm apart. Within this range, it is strong enough to overcome the powerful electrical repulsions. It is known as the *strong nuclear interaction*, to distinguish it from the other specifically nuclear interaction—the *weak* interaction—which causes the spontaneous disintegration of subnuclear particles (see WEAK INTERACTIONS). It is the strong nucleon interaction which is the source of energy in nuclear weapons and in nuclear reactors.

To investigate the workings of the strong nuclear interaction a beam of high-energy protons from a proton accelerator is directed at a target of liquid hydrogen (more protons) and scattered. At low energies, below 300 MeV in the laboratory, the protons are merely deflected by the strong nucleon-nucleon interaction. Above this energy, new particles are produced in the collision. The first to appear are the π -mesons, or pions. As the energy increases, more and more particles are found. The least massive are stable as far as the strong interaction is concerned, but they disintegrate through the weak interaction with mean lifetimes of about 10^{-10} second. The more massive particles decay via the strong interaction into other strongly interacting particles in about 10^{-23} second. These are tabulated in the article on ELEMENTARY PARTICLES.

Because of the strength of this interaction, it has not been possible to discover the details of the

corresponding dynamics. However, considerable progress has been made by studying the conservation laws which govern the collisions of strongly interacting particles.

The subnuclear particles are specified according to their properties which correspond to those physical quantities which are conserved (i.e., do not change) in any collision which is dominated by the strong interaction. These are typically the mass, which contributes to the energy, and the spin which is part of the total angular momentum. If a particle has spin J (in units of $\hbar/2\pi$) there are $2J+1$ possible states, corresponding to the orientations of the spin axis allowed by quantum mechanics. These states are distinguished by the magnitude of the component J_z which ranges by integers from $+J$ to $-J$.

Other conserved quantities are the electric charge, the so-called hypercharge, and the baryon number. These are also tabulated in the article ELEMENTARY PARTICLES.

These subnuclear particles appear in multiplets of nearly equal mass, but differing charge. Thus there are three pions (positive, negative and neutral) and two nucleons, one positive (the proton) and one neutral (the neutron). These are closely analogous to the $2J+1$ spin states of a particle of spin J and may be explained by attributing to each mass multiplet a spin I (isotopic spin) in an abstract space. The different charge states are then interpreted as the different "orientations" in this abstract space and are

specified by the $2I+1$ values of the component I_3 . Thus the pion has isotopic spin 1, with the three charge states specified by $I_3 = \pm 1, 0$. The nucleon has isotopic spin $I = 1/2$, with two charge states $I_3 = \pm 1/2$. Isotopic spin is conserved in strong interactions, just as total angular momentum is conserved. The conservation of angular momentum is related to the invariance of the whole colliding system with respect to its orientation in space. The conservation of isotopic spin is similarly equivalent to the statement that the strong interactions are invariant under a group of two-dimensional unitary transformations, known to group theorists as $SU(2)$.

It has been conjectured that the strong interactions are approximately invariant under a wider group of three-dimensional unitary transformations, $SU(3)$, which combines the notion of isotopic spin with that of hypercharge. According to this theory, the isotopic multiplets of particles of the same spin J can be combined into supermultiplets of roughly similar mass, which form hexagonal or triangular patterns when they are exhibited on a graphical plot of I_3 against Y . By 1963, three such supermultiplets had been established. They form octets of particles, with $J = 0, \frac{1}{2}$ and 1. (These are $\pi^+, \pi^0, \pi^-, \eta^0, K^+, K^0, K^-, \bar{K}^0, \Sigma^+, \Sigma^0, \Sigma^-, \Lambda^0, p, n, \Xi^0, \Xi^-, \rho^+, \rho^0, \rho^-, \phi^0, K^{*+}, K^{*0}, K^{*-}, \bar{K}^{*-}$.) At that time, the known particles of spin $J = 3/2$ formed a tenfold triangular multiplet, with one particle missing—the Ω^- . This missing particle was an isotopic singlet

FIG. 1. The well-established $SU(3)$ multiplets. In each of these, particles lying together on horizontal lines form sub-multiplets of $SU(2)$ (isotopic spin). The figures in brackets indicate the masses of the particles in MeV/c^2 .

($I=0$) with hypercharge minus two. It had remarkable physical properties very well defined so that its mass, mode of production, mean life time, and decay could all be predicted. This particle was discovered in 1964 exactly as forecasted, thus confirming the wider unitary scheme.

This scheme provides a kind of "periodic table" for the subnuclear particles. There are clearly very many of them, and the word "elementary" no longer seems appropriate, although it is still in common use. The establishment of "unitary symmetry" for strong interactions has been a great step forward in our understanding of the nuclear world, but it still leaves many questions unanswered. We still have no knowledge of the detailed working of the dynamics of the strong interactions and cannot even tell, for example, why the unitary multiplets, have the masses and spins which they do. There are, however, indications that progress can be made by further application of group theoretic ideas.

There is also the interesting question of whether the subnuclear particles are made up of a few simple entities, just as nuclei are composed of protons and neutrons. If so, unitary symmetry implies that there should be a triplet of particles of nearly equal mass, composed of an isotopic doublet and an isotopic singlet. However in order that the currently known particles should have integer charges (in units of the electron charge), these particles must have fractional charges of $2/3$ and $-1/3$. This is a revolutionary idea and nothing of the kind has been seen, with the energies available with present proton accelerators (about 30 BeV). However, it is conceivable that such particles could be discovered by the construction of yet larger proton accelerators.

SUPERCONDUCTIVITY

This article describes the experimental facts relating to superconductivity, our present theoretical understanding, and some practical applications. No attempt is made to follow historical order or to provide an exhaustive treatment; the references at the end of the article will help those who wish to pursue the subject further.

The most spectacular property of a superconductor is the total disappearance of its electrical resistance when it is cooled below a critical temperature T_c . Very careful measurements show that the electrical resistance of a superconductor is at least a factor 10^{17} smaller than the resistance of copper at room temperature and may therefore for all practical purposes be taken to be zero. Some 25 elements and a vast number of alloys and compounds have so far been discovered to be superconducting; examples are In, Sn, V, Mo, Nb-Zr alloys and Nb₃Sn. Transition temperatures range from a few thousandths of

a degree Kelvin (for certain Nb-Mo alloys) all the way to about 18°K for Nb₃Sn.

Another important property is the destruction of superconductivity by the application of a magnetic field equal to or greater than a critical field H_c . This H_c , for a given superconductor, is a function of the temperature given approximately by

$$H_c = H_0(1 - T^2/T_c^2) \quad (1)$$

where H_0 , the critical field at 0°K, is in general different for different superconductors and has values from a few gauss to a couple of thousand gauss. For applied magnetic fields less than H_c , the flux is excluded from the bulk of the superconducting sample, penetrating only to a small depth λ into the surface. The value of λ (called the penetration depth) is in the range 10^{-5} to 10^{-6} cm. Thus the magnetization curve for a superconductor is

$$B \text{ (inside)} = 0 \quad \text{for } H < H_c$$

$$B \text{ (inside)} = B \text{ (outside)} \text{ for } H > H_c$$

This magnetization behavior is reversible and cannot therefore be explained entirely on the basis of the zero resistance. The reversible magnetization behavior is called the Meissner effect.

The existence of the penetration depth λ suggests that a sample having at least one dimension less than λ should have unusual superconducting properties, and such is indeed the case. Thin superconducting films, of thickness d less than λ , have critical fields higher than the bulk critical field, approximately in the ratio of λ to d . This result follows qualitatively from the thermodynamics of the Meissner effect: the metal in the superconducting state has a lower free energy than in the normal state, and the transition to the normal state occurs when the energy needed to keep the flux out becomes equal to this free energy difference. But in the case of a thin film with $d < \lambda$, there is partial penetration of the flux into the film, and thus one must go to a higher applied field before the free energy difference is compensated by the magnetic energy.

It is clear that the existence of the critical field also implies the existence of a critical transport electrical current in a superconducting wire, i.e., that current I_c which produces the critical field H_c at the surface of the wire. For example, in a cylindrical wire of radius r , $I_c = \frac{1}{2}rH_c$. This result is called the Silsbee rule.

All of the above properties distinguish superconductors from "normal" metals. There is another very important distinction, which contains a clue to understanding some of the properties of superconductors. In a normal metal at 0°K, the electrons, which obey Fermi statistics, occupy all available states of energy below a certain maximum energy called the Fermi energy ζ . Raising the temperature of the metal causes electrons to be singly excited to states just above the Fermi energy. There is for all practical purposes a continuum of such excited energy states available above the Fermi energy. The situation is quite different in a superconductor; it turns

out that in a superconductor, the lowest excited state for an electron is separated by an energy gap ϵ from the ground state. The existence of this gap in the excitation spectrum has been confirmed by a wide range of measurements: electronic heat capacity, thermal conductivity, ultrasonic attenuation, far infrared and microwave absorption, and tunneling. The energy gap is a monotonically decreasing function of temperature, having a value $\sim 3.5kT_c$ at 0°K (where k is the Boltzmann constant) and vanishing at T_c (see ENERGY LEVELS).

The superconducting state has a lower entropy than the normal state, and therefore one concludes that superconducting electrons are in a more ordered state. Without, for the present, inquiring more deeply into the nature of this ordering, one can state that a spatial change in this order produced say by a magnetic field will occur, not discontinuously, but over a finite distance ξ , which is called the *coherence length*. The coherence length represents the range of order in the superconducting state and is typically about 10^{-3} cm, though we shall see later that it can in some superconductors take much lower values and lead to some remarkable properties.

Measurements of the transition temperature on different ISOTOPES of the same superconductor showed that T_c is proportional to M^{-1} , where M is the isotopic mass. This isotope effect suggests that the mechanism underlying superconductivity must involve the properties of the lattice, in addition to those of the electrons. Another indication of this is given by the behavior of allotropic modifications of the same element: white tin is superconducting, while grey tin is not, and the hexagonal and face-centered cubic phases of lanthanum have different transition temperatures. A third, and most striking, indication is that the current vs voltage characteristic of a superconducting tunneling junction shows a structure which is intimately related to the phonon spectrum of the superconductor.

The superconducting properties of alloys present a bewildering variety of phenomena. They show a great deal of magnetic hysteresis, with little indication of a perfect Meissner effect. The Silsbee rule is inapplicable, and the resistive transition occurs at fields generally very much higher than in pure superconductors. For example, a wire of Nb_3Sn can carry a current of 10^5 amperes/cm² in an applied field of 100 kilogauss, while a similar wire of lead would carry about 10^3 amperes/cm² in a field of only 100 gauss. When experiments are done using well-annealed (preferably single-crystal) alloys, it is found that the critical currents drop considerably, and the magnetic behavior becomes reversible but still quite unlike that of pure superconductors. The flux is excluded from the interior of the sample up to a well-defined field H_{c1} . When the applied field is raised further, flux begins to penetrate, even though the resistance remains zero, until a second critical field H_{c2} is reached, at which the flux penetration is complete, and normal resistance is abruptly restored.

The theory of superconductivity has developed along two lines, the phenomenological and the microscopic. The phenomenological treatment was initiated by F. London, who modified the Maxwell electromagnetic equations so as to allow for the Meissner effect. His theory explained the existence and order of magnitude of the penetration depth, and gave a qualitative account of some of the electrodynamic properties. The treatment was extended by V. L. Ginzburg and L. D. Landau, and by A. B. Pippard, who in particular emphasized the concept of the range of coherence. A. A. Abrikosov used these ideas to develop a model for alloy superconductors. He showed that if the electronic structure of the superconductor were such that the coherence length ξ becomes smaller than the penetration depth λ , one would get magnetic behavior similar to that observed in alloys, with two critical fields H_{c1} and H_{c2} . The problem of high critical currents in unannealed (or otherwise metallurgically imperfect) alloys and compounds is more complicated because it involves the interaction between the microscopic metallurgical structure and the superconducting properties. This is an area of great research activity because of the technological implication to be mentioned later.

The microscopic theory of superconductivity was initiated by H. Fröhlich, who first recognized the importance of the interactions of electrons with lattice vibrations and in fact predicted the isotope effect before its experimental observation. The detailed microscopic theory was developed by J. Bardeen, L. N. Cooper and J. R. Schrieffer in 1957, and represents one of the outstanding landmarks in the modern theory of solids. The BCS theory, as it is called, considers a system of electrons interacting with the PHONONS, which are the quantized vibrations of the lattice. There is a screened coulomb repulsion between pairs of electrons, but in addition there is also an attraction between them via the electron-phonon interaction. If the net effect of these two interactions is attractive, then the lowest energy state of the electron system has a strong correlation between pairs of electrons with equal and opposite momenta and opposite spin and having energies within the range $k\theta$ (where θ is the Debye temperature) about the Fermi energy. This correlation causes a lowering of the energy of each of these Cooper pairs (named after L. N. Cooper who first pointed out their existence on the basis of some general arguments) by an amount ϵ relative to the Fermi energy. The energy ϵ may be regarded as the binding energy of the pair, and is therefore the minimum energy which must be supplied in order to raise an electron to an excited state. We see thus that the experimentally observed energy gap follows from the theory. The magnitude ϵ_0 of the gap at 0°K is

$$\epsilon_0 \approx 4k\theta \exp \left(-\frac{1}{NV} \right)$$

where N is the density of electronic states at the Fermi energy and V is the net electron-electron

interaction energy. The superconducting transition temperature T_c is given by

$$3.5kT_c \approx \epsilon_0$$

It has been shown that the BCS theory does lead to the phenomenological equations of London, Pippard and Ginzburg and Landau, and one may therefore state that the basic phenomena of superconductivity are now understood from a microscopic point of view, i.e., in terms of the atomic and electronic structure of solids. It is true, however, that we cannot yet, *ab initio*, calculate V for a given metal and therefore predict whether it will be superconducting or not. The difficulty here is our ignorance of the exact wave functions to be used in describing the electrons and phonons in a specific metal, and their interactions. However, we believe that the problem is soluble in principle at least.

The range of coherence follows naturally from the BCS theory, and we see now why it becomes short in alloys. The electron mean free path is much shorter in an alloy than in a pure metal, and electron scattering tends to break up the correlated pairs, so that for very short mean free paths one would expect the coherence length to become comparable to the mean free path. Then the ratio $\kappa \approx \lambda/\xi$ (called the Ginzburg-Landau order parameter) becomes greater than unity, and the observed magnetic properties of alloy superconductors can be derived. The two kinds of superconductors, namely those with $\kappa < 1/\sqrt{2}$ and those with $\kappa > 1/\sqrt{2}$ (the inequalities follow from the detailed theory) are called respectively type I and type II superconductors.

There have been several attempts at technological applications of superconductors. The most spectacularly successful one is the use of certain type II superconductors like Nb-Zr and Nb-Ti alloys, and Nb₃Sn, in making electromagnets. In a conventional electromagnet employing normal conductors, the entire electric power applied to the magnet is consumed as Joule heating. For a magnet to produce 100 kilogauss in a reasonable volume, the power requirement can run into megawatts. In striking contrast, a superconducting magnet develops no Joule heat because its resistance is zero. Indeed, if such a magnet has a superconducting shunt placed across it after it is energized, the external power supply can be removed, and the current continues to flow indefinitely through the magnet and shunt, maintaining the field constant. Superconducting magnets have already been constructed producing fields of over 100 kilogauss in usable volumes. There is a natural upper limit to the critical field possible in such superconductors, given by the paramagnetic energy of the electrons (due to their spin moment) in the normal state becoming equal to the condensation energy of the Cooper pairs in the superconducting state. This leads to a limit of about 360 kilogauss for a superconductor with a T_c of 20° K.

The possibility of a persistent current in a superconducting ring, and the sharpness and

speed of the change in resistance at the superconducting to normal transition, have led to consideration of superconductors for memory and logic circuits in computers. Further work, mainly of a technological nature, is needed before practical superconducting computers can be built.

SUPERFLUIDITY

Superfluidity is a term used to describe a property of condensed matter in which a resistanceless flow of current occurs. The mass-four isotope of helium in the liquid state plus some twenty-three metallic elements are presently known to exhibit this phenomenon. In the case of liquid helium, these currents are hydrodynamic; for the metallic elements, they consist of electron streams. The effect occurs only at very low temperatures in the vicinity of the absolute zero (-273.16°C or 0°K). In the case of helium, the maximum temperature at which the effect occurs is about 2.2°K ; for metals the highest temperature is in the vicinity of 20°K .

If one of these metals (called superconductors) is cast in the form of a ring and an external magnetic field is applied perpendicular to its plane and then removed, a current will flow round the ring induced by Faraday induction. This current will produce a magnetic field, proportional to the current, and the size of the current may be observed by measuring this field. Were the ring (e.g.,

one made of Pb) at a temperature above 7.2°K, this current and field would decay to zero in a fraction of a second. But with the metal at a temperature below 7.2°K before the external field is removed, this current shows no signs of decay even when observations extend over a period of a year. As a result of such measurements, it has been estimated that it would require 10^{99} years for the supercurrent to decay! To the best of our knowledge, therefore, the lifetime of these "persistent" currents is infinite. The persistent or frictionless currents in superconductors are not a recent discovery, they were observed first some 50 years ago (see SUPERCONDUCTIVITY).

In the case of liquid helium, these currents are, as mentioned, hydrodynamic, i.e., they consist of streams of neutral (uncharged) helium atoms flowing in rings. Since, unlike electrons, the helium atoms carry no charge, there is no resulting magnetic field. This makes such currents much more difficult to create and detect. Nevertheless, as a result of research carried out here and in England in the past five or six years, the existence of these supercurrents in liquid helium has definitely been proved. These currents have very recently (1964) been observed for periods as long as 12 hours, a time of the order of 10^3 shorter than is the case for electron currents. Nevertheless, our present belief is that these hydrodynamic currents also possess an infinite lifetime.

As mentioned, the empirical discovery of infinite-lifetime electron currents is of considerable antiquity, and from the beginning, many attempts have been made to explain the effect theoretically. Until very recently all such attempts have failed completely, and as a matter of fact, the theoretical picture is still not completely satisfactory. Nevertheless, immense progress in this direction has occurred in the past decade largely as the result of work in the U.S.A., England and Russia.

Although superfluidity in liquid helium is important to our basic understanding of the phenomenon, it is the effect in superconductors which arouses the most interest. This is due, in part at least, to the possible practical applications to which the effect might lead. In ordinary conductors (e.g., copper), the flow of an electric current is always accompanied by energy dissipation. The supercurrents propagate with no such power loss; superconducting transmission lines would be an economic advance of the first order. However, they would require "room temperature" superconductors, and unfortunately, modern theories, while they do not absolutely prohibit such, render their occurrence most unlikely.

In other ways, however, superconductors have already proved of practical value. Since the currents once created are there for all time, they have fairly obvious use as memory elements in computers. Again the persistent currents form a sort of super gyroscope more perfect than any so far devised. In recent years alloy superconductors have been found (e.g., Nb₃Sn) which can support persistent currents even in the presence of intense

magnetic fields of the order of 100 000 gauss. It is, generally speaking, a property of elemental superconductors that the persistent current is quenched in fields of a few hundred gauss; the situation in some alloys like the above is very different.

This has led to the development of intense field solenoidal magnets which maintain their magnetic fields with zero energy dissipation. A conventional electromagnet of the same size would consume many hundreds of kilowatts. This discovery has important consequences in several areas of physics.

Both aspects of superfluidity find their theoretical explanation in what is called a two-fluid theoretical model. We suppose that liquid helium and superconductors are quantum systems possessing a zero energy ground state plus a series of available states of higher energy called normal or excited states. The occupancy of the ground state is zero above the superfluid transition temperature (2.2 K for liquid helium) but grows steadily as the temperature is lowered. At absolute zero, the whole system is in the ground state. At any finite temperature, below transition, the system is in a mixture of ground and excited states. It is the particles in the ground state which form the persistent current.

A simple, though not entirely accurate, *raison d'être* for the persistent currents lies in the fact that in the ground state, all the very many particles possess the same single wave function. It follows from this that such particles are not easily scattered out of the ground state—a finite amount of energy is required. Such an assembly will not readily interact with outside particles including those in excited states. Since fluid friction or viscosity is due to particle momentum interchange between neighboring layers of liquid, it follows that particles in the ground state will possess zero viscosity. This, in turn, means frictionless flow.

An assembly of particles obeying Bose-Einstein statistics will, below a certain temperature, possess a ground state like the one postulated above. It is known that Bose-Einstein statistics apply only to particles which possess zero (or integral) spin. The neutral He⁴ atom possess zero spin. The isotope He³ (spin 1/2) does not; and, in fact, liquid He³ is not a superfluid. But this is also true of electrons which possess half integral spin and obey a very different statistic (Fermi-Dirac). In this statistic no more than two electrons can possess the same wave function. Hence a ground state, in the above sense, can clearly not exist. Thus according to our model, superfluid flow of electrons cannot occur—but it does!

A way out of this dilemma was suggested nearly 20 years ago. Namely, combine the electrons into pairs, with opposite spins. The resulting "particle" is then a boson and may properly reside in the ground state. The reason why this idea was not accepted by theoretical physicists until very recently was because no mechanism could be found by which the electrons could be induced to form pairs. It turns out that the required mechanism arises as a result of a phonon

(quantized lattice wave) emitted by one electron and absorbed by another at some other place. This couples the two together.

As mentioned, none of the current theories clearly explains persistent currents. It is not at all evident that their lifetimes should be infinite. It is thought by some that a better formulation for statistical mechanics than presently exists may be necessary before this becomes possible.

A system of persistent currents distinguished by the fact that many particles possess the same wave function constitutes a quantum effect on a hitherto unknown macroscopic scale. In other words, superfluids should exhibit quantum effects of such size that they are readily amenable to experimentation. Within the past few years, two such effects, one in each of the superfluids, have been found. A long thin cylinder with a hole along the axis (i.e., a tube) is similar to the previously mentioned superconducting ring in that persistent currents may also be produced in it. If the length of the cylinder is large compared to the diameter of the hole, the "trapped" magnetic field due to the persistent current is substantially uniform. The flux is the product of this field by the area of the hole.

As a consequence of the fact that the particles producing the current all possess the same wave function, it may be shown that this flux is quantized in integral multiples of hc/q (h = Planck's constant, c = velocity of light, q = charge on the particles).

This prediction has recently (1961) been confirmed experimentally. Further, these experiments show that $q = 2e$, where e is the charge on an electron. Thus the pair hypothesis is very nicely proven.

An interesting consequence of the above effect is that it is impossible to have any field (below a certain value depending on the size of the hole) at all in the cavity. Thus the measurements show that $hc/q \approx 2 \times 10^{-7}$ so that with a hole 1μ in diameter, a field less than about 13 gauss could not exist. We should therefore have a truly field-free space.

A very similar situation, due fundamentally to the same cause, exists for the hydrodynamic currents in liquid helium. In this case, it is the hydrodynamic "circulation" which is quantized in units of h/m (h = Planck's constant, m = helium atom mass). By circulation we mean $\oint \mathbf{v} \cdot d\mathbf{l}$ where \mathbf{v} is the velocity of the atom in the ring-current and $d\mathbf{l}$ is a line element of the periphery of the ring. This effect has also been observed quite recently (1958) in laboratory experiments.

There is also a surprising consequence connected with this effect. Suppose the helium was being rotated in its containing vessel at a temperature above 2.2°K. Here the helium is "classical" and would rotate, like any other familiar liquid, at the same angular velocity as the vessel. Suppose, now, that the helium was cooled down to near 0°K with the vessel still rotating. If the initial speed were less than that required to produce one quantum of circulation, the rotating

helium would come to rest while the container continued to rotate!

This is analogous to the behavior of the magnetic flux on the superconductor, the angular velocity being the quantity analogous to the magnetic field. To be sure, the above experiment has, to date, not been performed, but this is entirely due to difficulties with the existing instrumentation. With advances in technique, it seems very likely that the experiment can eventually be performed, and there is little doubt that the result predicted will be observed.

SURFACE PHYSICS

Thermodynamics and Simplified Models of Surfaces. The reversible work required to create a unit area of solid surface at a constant volume, temperature and chemical potential is customarily called the surface tension and denoted as γ . The Helmholtz free energy per unit area of surface, f_s , is thus:

$$f_s = \gamma + \sum_i \mu_i \Gamma_i$$

where μ_i and Γ_i are respectively the chemical potential and excess surface density of the i th component. For one-component systems, $\gamma = f_s$, Γ_i then being 0. For a liquid, γ is equal to the surface stress; in a solid, this is not true, and in fact, components of the surface stress tensor may be zero or of either sign. The above definitions are somewhat inadequate for a general surface. The ambiguities in the definition of surface properties have been treated by Gibbs and discussed in several places.^{1,2}

Crudely the surface tension arises from the fact that the surface atoms are bound to fewer neighbors than are atoms in the bulk phase. Assuming neighbor-neighbor interactions and no surface distortion, one may estimate γ by counting broken bonds which yields, for a close packed surface, $A\gamma \approx 1/4 \frac{L_0}{N}$ where A is the area per surface atom, L_0 is molar heat of sublimation and N is Avagadro's number. These assumptions are obviously inadequate, and the estimate gives only the order of magnitude of γ which for metals is on the order of several hundred to several thousand ergs per square centimeter.

For a crystal, γ is a function of the crystallographic orientation of the surface. A surface with a mean orientation the same as that of a low index face is usually thought to be smooth. For surfaces inclined with respect to low index planes there will be atomic planes which terminate on the surface at steps. In the crude picture, additional broken bonds are associated with the steps and

thus the energy will be higher than for a close-packed plane. Again, counting broken bonds, and assuming steps widely separated so as not to interact, leads to:

$$\gamma(\theta) = \gamma_0 \cos \theta + \alpha \sin |\theta|; \theta \ll 1$$

where γ_0 is the surface tension of the low index face, α is proportional to the energy per step, and $\gamma(\theta)$ is the surface tension for a surface inclined by an angle θ from the low index face. Thus, on a polar plot of $\gamma(\theta)$ vs the orientation of the normal to the surface, there will be cusps at the orientations of close-packed planes. At finite temperature, the cusps disappear because of entropy considerations.

The surface tension is changed by adsorption on the surface in accordance with Gibbs' adsorption equation:

$$d\gamma = -s_s dT - \sum_i \Gamma_i d\mu_i$$

where s_s is the specific surface entropy. Thus, at constant temperature, introduction of a component which is adsorbed on the surface reduces γ and generally changes the shape of the γ plot since the Γ_i depend on the orientation of the surface.

The equilibrium shape of a crystal depends on the orientation dependence of γ and may be determined graphically by the Wulff construction. In the polar plot of the γ diagram mentioned above one constructs planes perpendicular to all radius vectors at the point at which they intersect the γ plot. Then the figure containing all points which may be reached from the origin without crossing any such plane has the same shape as the equilibrium crystal. Herring¹ has discussed proofs of the Wulff construction and possible equilibrium shapes of crystals.

A smooth surface of an orientation not represented in the Wulff equilibrium shape will be able to reduce its surface energy by developing facets, keeping the same mean orientation. Such faceting may be observed if the kinetics allow it in reasonable time and if other processes such as selective evaporation or chemical reactions do not allow the development of the equilibrium surface. When faceting driven by the surface energy is observed, it should yield information about the anisotropy of γ .

Atoms may be transported from one surface site to another by (1) transport through a vapor phase, (2) diffusion through the bulk, and (3) surface diffusion. Only the last is considered briefly here. The surface self-diffusion is thermally activated and often is much faster than bulk diffusion and vapor transport. The situation is somewhat complicated by the fact that atoms may occupy a variety of sites on a surface, i.e., (1) as an adatom on an otherwise smooth surface, (2) as an atom on a step, (3) as an atom at a jog in the step, (4) as an atom in a step, or (5) as an atom within a smooth layer. A diffusing atom will occupy each type of these sites in its motion over the surface, and for each type, there will be a

different average jump frequency. In a given experimental situation, the diffusion will depend on the population of atoms in the various sites which may not be in equilibrium. Furthermore, the diffusion will not necessarily be isotropic in the plane of the surface and will be affected by adsorbed impurities.

The surface self diffusion is measured experimentally by observing development of grain boundary grooves, smoothing of scratches, thermal faceting, blunting of field-emission microscope tips, by radioactive tracer techniques and by field ion-microscopy. N. A. Gjostein³ has written a review of surface diffusion and has summarized available experimental data.

Atomic Structure of Surfaces. In the previous paragraphs, reference has been made to surface structures as if they resulted by simply terminating the bulk structure along a plane with perhaps some terraces, steps and jogs. Recently, mainly through slow electron diffraction experiments, considerable detailed information concerning actual structures has become available. Within several atomic layers of the surfaces, real structures may differ from those of the bulk by small distortions or may be completely "reconstructed." Elizabeth A. Wood has proposed conventions for describing surface structures which are followed here.⁴ The region of the material in which the structure is periodic in the direction normal to the surface (the structure is triperiodic) is the substrate. The region in which the structure is diperiodic is called the selvage. Whereas in a triperiodic structure unit cells are arranged in one of the fourteen Bravais lattices, in a diperiodic structure unit meshes are arranged in one of five nets. The five nets are described in Table I.

Most of the usual crystallographic notation of triperiodic structures can be carried over to diperiodic systems with only obvious modifications. These are listed by Wood. The reciprocal lattice becomes a family of rods normal to the net. The Miller indices of rows are customarily given in terms of the substrate, and since surface structures often have large unit meshes, fractional Miller indices are used.

The surface structure usually bears a close relationship to the substrate, and this fact is used in a convenient notation to designate the surface structure. The orientation of the substrate plane parallel to the surface is specified first, then the ratios of the lengths of unit mesh vectors of the surface structures and of the substrate plane, and finally the chemical symbol of any adsorbed atoms if present. As an example, Ni(110) 3×1 O refers to a surface structure on the (110) face of nickel with unit mesh vectors parallel to the substrate, with

$$|\vec{a}_{\text{surface}}|/|\vec{a}_{\text{substrate}}| = 3,$$

$$\text{and } |\vec{b}_{\text{surface}}|/|\vec{b}_{\text{substrate}}| = 1$$

and containing adsorbed oxygen. If the two ratios above are the same, only their common value is given.

TABLE I (TAKEN FROM WOOD'S PAPER)*

Shape of mesh	Lattice symbol†	Choice of Axis	Nature of Axis and Angles	Name of Corresponding System
General parallelogram	p	$a \neq b$	$a \neq b$ $\gamma \neq 90^\circ$	Oblique
Rectangular	p	Shortest two mutually perpendicular vectors $a \neq b$	$a \neq b$ $\gamma \neq 90^\circ$	Rectangular
Square	p	Shortest two mutually perpendicular vectors	$a = b$ $\gamma = 90^\circ$	Square
120° angle rhombus	p	Shortest two vectors at 120° to each other	$a = b$ $\gamma = 120^\circ$	Hexagonal

* From Wood, Elizabeth A., "Vocabulary of Surface Crystallography," *J. Appl. Phys.*, 35, 1306 (1964).

† p refers to a primitive mesh and c to a centered one.

The surface structure of several materials and adsorbed layers on them have been investigated by low-energy electron diffraction techniques. Summaries of the results and references to them are given by J. J. Lander⁵ and in reference 6.

Surfaces of the dense planes of metals, layered materials such as graphite and cleavage planes of ionic crystals generally differ by only small distortions from the corresponding bulk structures. As examples: Peria and Johnson⁶ find that the low-energy electron diffraction from the cleavage plane of MgO is best fit by displacing the second layer of magnesium ions 0.35Å toward the surface, the oxygen ions remaining fixed; Germer and Mac Rae⁸ suggest that the spacing between the first and second atomic layers of clean nickel is 5 per cent greater than in the bulk material. These results should perhaps be considered as tentative since a completely satisfactory understanding of the scattered intensities in slow electron diffraction experiments is not yet available.

Covalently bonded materials are more likely to have "reconstructed" surface structures as might be expected from the unfavorable energy of structures with broken bonds. There may be a wide variety of such structures for surfaces of each orientation, and prediction of such structures from first principles is as yet impossible. Interesting examples of such structures are the surfaces of freshly cleaved and then annealed silicon. In a (111) surface cleaved at room temperature in vacuum, alternate "rows of top layer atoms are brought into the adjacent rows and given double bonds to the atoms already there. The broken bonds of atoms in the row below are then restored by displacing these atoms to form paired rows."⁹ It is interesting that this structure has twofold rotational symmetry on a substrate of threefold symmetry. At 700°C, the structure is "reconstructed" to a more stable one, Si (111)-7 or Si (111)-5 which are made up of "warped benzene rings", each unit having three atoms from both the first and second layers of atoms. The outer layer contains only about three-fourths as many atoms as the freshly cleaved structure, and

therefore diffusion of atoms out of the surface is required for its formation.

The variety and complexity of actual surface structures illustrates the serious shortcoming of those calculations of surface properties based on simplified models.

Electronic Structure. The electronic structure in the vicinity of the surface differs from that which would result from simply terminating the crystal along a plane and allowing no subsequent relaxation. In a metal, the electronic charge distribution does not end abruptly at the surface, but decreases smoothly and extends beyond the boundaries of the Wigner-Seitz cells of the surface atoms. This leads to a surface dipole layer, negative on the outside, which, along with the image potential, is the major contribution of the surface to the work function of the metal. This contribution is the order of a few tenths of an electron volt and is the order of 10 per cent of the observed work function. The larger contributions are due to the bulk properties and are not discussed here. In a metal, the thickness of the region in which the electron density differs from its bulk value is on the order of the interatomic spacing, which is of course the order of the wavelength of the most energetic conduction electrons. This smooth decrease of the charge density at the surface is a result of a compromise between the higher electrostatic energy of the dipole layer and the kinetic energy it would require to make a steeper boundary. This same compromise will make the boundary of the electron distribution smoother in the directions parallel to the surface than the boundary of the ion cores. The hill and valley structure of atomically rough surfaces then gives an additional dipole layer with the positive side outward. Thus, rougher surfaces have lower work functions than more closely packed, smoother surfaces.

The electronic distribution makes a contribution to the surface energy, but realistic calculations are very difficult and the usual discussions are for a free electron gas model. Because the conduction electrons adjust easily to the potential at the surface, metals have surface energies of only 1/2 to 2/3 that which

would be predicted from the sublimation energy. For both the surface energy and the work function, the lattice potential and correlation and exchange terms are important. The theoretical approaches to these problems are reviewed by Ewald and Juretschke¹⁰ and by Herring.¹¹

For the half-infinite crystal with a periodic potential, there is the possibility that there are localized states on the surface with energies within the band gaps of the bulk structure. The wave functions of these states are exponentially damped on both sides of the surface. The area density of such states should be the same order as the density of surface atoms. They are called Tamm states after I. Tamm who first investigated them for a one dimensional Kronig-Penney model. The conditions for the existence of surface states for actual crystals are not completely clear, but in some models they appear if the energy bands of the bulk overlap or if the surface atomic structure is different from the bulk, resulting in a potential trough. Recent discussions of both theoretical and experimental aspects of surface states can be found in the papers of reference 6.

Surface states are particularly important in semiconductors, and there has been extensive work on Germanium crystals¹². They are of two types: (1) "fast" states which occur on atomically clean surfaces or at the interface between the semiconductor and its oxide layer, which are thus in good electrical contact with the bulk, and which therefore may adjust their occupation in the order of 10^{-6} to 10^{-8} second following a disturbance; and (2) "slow" states on the outer surface of the oxide layer and for which changes in the occupation after a disturbance are much slower. The observed density of the "fast" states is a few orders of magnitude smaller than the surface density of atoms so they are not truly Tamm states, but may be due to imperfections or deformations of the surface.

There will be a surface space charge region which shields any charge localized in the surface states and which will, because of the low density of free carriers in the semiconductor, extend into the bulk to depths usually the order of 10^{-5} cm. The energy bands bend through this region in order to give the requisite shielding charge. The bending of the bands will lead to regions in which the conductivity type (n or p) may be opposite that of the bulk (i.e., an inversion layer) or in which the conductivity is more strongly of the same type as the bulk (i.e., an accumulation layer) or, finally, in an intermediate case, in a region where the conductance of the specimen is decreased, called an exhaustion layer. The energies, densities, and trapping and recombination cross sections of the surface states can be investigated by measurements of various electrical properties. The discussion of these investigations is beyond the scope of this article and the reader is referred to recent reviews by Watkins,¹² Law,¹³ and by Zemel.¹⁴

SURFACE TENSION

Surface tension results from the tendency of a liquid surface to contract. It is given by the tension σ across a unit length of a line on the surface of a liquid. The surface tension of a liquid depends on the temperature and diminishes as temperature increases and becomes 0 at the critical temperature. For water σ is 0.073 newtons/m at 20°C, and for mercury it is 0.47 newtons/m at 18°C.

Surface tension is intimately connected with capillarity, that is, rise or depression of liquid inside a tube of small bore when the tube is dipped into the liquid. Another factor which is related to this phenomenon is the angle of contact. If a liquid is in contact with a solid and with air along a line, the angle θ between the solid-liquid interface and the liquid-air interface is called the angle of contact (Fig. 1). If $\theta = 0$, the liquid is said to wet the tube thoroughly. If θ is less than 90°, the liquid rises in the capillary, and if θ is greater than 90°, the liquid does not wet the solid but is depressed in the tube. For mercury on glass, the angle of contact is 140°, so that mercury is depressed when a glass capillary is dipped into mercury. The rise h of the liquid in the capillary is given by $h = 2\sigma \cos \theta / r \rho g$, where r is the radius of the tube, ρ the density of the liquid, and g is the acceleration due to gravity.

Surface tension can be explained on the basis of molecular theory. If the surface area of liquid is

FIG. 1. Capillarity.

expanded, some of the molecules inside the liquid rise to the surface. Because a molecule inside a mass of liquid is under the forces of the surrounding molecules while a molecule on the surface is only partly surrounded by other molecules, work is necessary to bring molecules from the inside to the surface. This indicates that force must be applied along the surface in order to increase the area of the surface. This force appears as tension on the surface and when expressed as tension per unit length of a line lying on the surface, it is called the surface tension of the liquid.

The molecular theory of surface tension has been dealt with since the time of Laplace (1749–1827). As a result of the clarification of the nature of intermolecular forces by quantum mechanics and of the recent development in the study of molecular distribution in liquids, the nature and the value of surface tension have come to be understood from a molecular point of view.

Surface tension is closely associated with a sudden but continuous change in the density from the value for bulk liquid to the value for the gaseous state in traversing the surface (Fig. 2). As a result of this inhomogeneity, the stress across a strip parallel to the boundary— p_N per unit area—is different from that across a strip perpendicular to the boundary— p_T per unit area. This is in contrast with the case of homogeneous fluid in which the stress across any elementary plane has the same value regardless of the direction of the plane.

The stress p_T is a function of the coordinate z , the z -axis being taken normal to the surface and directed from liquid to vapor. The stress p_N is constant throughout the liquid and the vapor. The figure shows the stress p_N and p_T . The stress

$p_T(z)$ as function of z is also shown on the left side of the Figure.

The surface tension is given by integrating the difference $p_N - p_T(z)$ over z :

$$\sigma = \int_{(\text{liquid})}^{(\text{vapor})} [p_N - p_T(z)] dz$$

A statistical mechanical treatment of the system leads to the expression of p_N and p_T in terms of intermolecular forces, density distribution, and

FIG. 2. Stress relationships in surface tension.

the distribution of other molecules around a molecule which is located at a position z . The change of the number density and the distribution

of other molecules around a central molecule at z are problems which have not yet been completely solved. Some simplifying assumptions such as to assume the transition layer to be a mathematical surface of density discontinuity have made the theory more amenable to numerical calculations. It can be said that so far as such simple liquids as liquid argon are concerned, the values of surface tension have been calculated theoretically in fair agreement with observed values.

SYMBOLS, UNITS AND NOMENCLATURE IN PHYSICS

Introduction. International communication and cooperation in science continue to grow in importance. Not the least important aspect of this cooperation is uniformity of international usage of symbols, units, and nomenclature in physics. The proliferation of research in countries throughout the world makes the problem of uniformity of usage a vital one in the dissemination of scientific literature, for it is obvious that much time and effort can be wasted in misunderstandings arising from terminology.

The recommendations given here are primarily those of the Commission on Symbols, Units and Nomenclature of the International Union of Pure and Applied Physics* as approved by the General Assemblies of IUPAP in 1960 and 1963. There is agreement on most of these recommendations among the following international organizations:

- (1) International Organization for Standardization, Technical Committee 12;
- (2) General Conference on Weights and Measures;
- (3) International Union of Pure and Applied Chemistry;
- (4) International Electrotechnical Commission, Technical Committees 24, 25;
- (5) International Commission on Illumination.

Physical Quantities—General Recommendations. A physical quantity, represented by a symbol, is equivalent to the product of a numerical value and a unit. For dimensionless physical quantities, the unit often has no name or symbol and is not explicitly indicated.

* UIP 9; SUN 61-44; reproduced in *Phys. Today*, 15, No. 6, 19 (June 1962).

EXAMPLES:

$$E = 200 \text{ erg} \quad n_{\text{qu.}} = 1.55$$

$$F = 27 \text{ N} \quad \nu = 3 \times 10^8 \text{ Hz}$$

Symbols for Physical Quantities—General Rules.

(1) Symbols for physical quantities should be single letters of the Latin or Greek alphabet with or without modifying signs: subscripts, superscripts, dashes, etc.

REMARK: (a) An exception to this rule consists of the two-letter symbols, which are sometimes used to represent dimensionless combinations of physical quantities. If such a symbol, composed of two letters, appears as a factor in a product, it is recommended to separate this symbol from the other symbols by a dot or by brackets or by a space.

(b) Abbreviations, i.e., shortened forms of names or expressions, such as p.f. for partition function should not be used in physical equations. These abbreviations in the text should be written in ordinary Roman type.

(2) Symbols for physical quantities should be printed in *italic* (i.e., sloping) type.

REMARK: Subscripts and superscripts should be in italic type when they are symbols for physical quantities or when they are running indices: e.g., C_p where p represents pressure but C_k where g means gas; g_{ik} where i and k are running indices but E_k where k means kinetic.

(3) Symbols for vectors and tensors: Special type fonts are recommended for these quantities but not for their components:

(a) Vectors should be printed in boldface type.

(b) Tensors of the second rank[†] should be printed in sans serif type.

* *Simple Mathematical Operations.* (1) Addition and subtraction of two physical quantities are indicated by:

$$a + b \text{ and } a - b$$

(2) Multiplication of two physical quantities may be indicated in one of the following ways:

$$ab \quad a b \quad a \cdot b \quad a \times b$$

REMARK: The various products of vectors and tensors may be written in the following ways:

Scalar product of vectors A and B : $A \cdot B$

Vector product of vectors A and B : $A \times B$

Dyadic product of vectors A and B : AB

Scalar product of tensors S and T ($\sum_k S_{ik} T_{ki}$): $S : T$

Tensor product of tensors S and T ($\sum_k S_{ik} T_{ki}$): $S \cdot T$

Product of tensor S and vector A ($\sum_k S_{ik} A_k$): $S \cdot A$

(3) Division of one quantity by another quantity may be indicated in one of the following ways:

$$\frac{a}{b} \quad a/b \quad a b^{-1} \quad a(1/b)$$

These procedures can be extended to cases where one of the quantities or both are themselves products, quotients, sums or differences of other quantities.

If necessary, brackets have to be used in accordance with the rules of mathematics.

If the solidus is used to separate the numerator from the denominator and if there is any doubt where the numerator starts or where the denominator ends, brackets should be used.

EXAMPLES:

Expressions with a Horizontal Bar Same Expressions with a Solidus

$$\frac{a}{bcd}$$

$$a/bcd$$

$$\frac{2}{9} \sin kx, \frac{1}{2} RT$$

$$(2/9) \sin kx, (1/2)RT \text{ or } RT/2$$

$$\frac{a}{b} \cdots c$$

$$a/b \cdots c$$

$$\frac{a}{b-c}$$

$$a/(b-c)$$

$$\frac{a-b}{c-d}$$

$$(a-b)/(c-d)$$

$$\frac{a}{c} \cdots \frac{b}{d}$$

$$a/c \cdots b/d$$

REMARK: It is recommended that in expressions like:

$$\sin \{2\pi(x-x_0)/\lambda\}, \quad \exp \{(r-r_0)/\sigma\},$$

$$\exp \{-V(r)/kT\}, \quad \sqrt{\epsilon/c^2}$$

the argument should always be placed between brackets, except when the argument is a simple product of two quantities, e.g., $\sin kx$. When the horizontal bar above the square root is used no brackets are needed.

Units—General Recommendations. *Symbols for Units—General Rules.* (1) *Symbols for units of physical quantities should be printed in roman (upright) type.*

(2) *Symbols for units should not contain a final full stop and should remain unaltered in the plural, e.g., 7 cm and not 7 cms.*

(3) *Symbols for units should be printed in lower case roman (upright) type. However, the symbol for a unit, derived from a proper name, should start with a capital roman letter, e.g., m (meter); A (ampere); Wb (weber); Hz (hertz).*

Prefixes—General Rules. (1) *The following prefixes should be used to indicate decimal fractions or multiples of a unit.*

$$\text{deci} \quad (=10^{-1}) \text{ d}$$

$$\text{centi} \quad (=10^{-2}) \text{ c}$$

$$\text{milli} \quad (=10^{-3}) \text{ m}$$

$$\text{micro} \quad (=10^{-6}) \mu$$

$$\text{nano} \quad (=10^{-9}) \text{ n}$$

$$\text{pico} \quad (=10^{-12}) \text{ p}$$

$$\text{femto} \quad (=10^{-15}) \text{ f}$$

$$\text{atto} \quad (=10^{-18}) \text{ a}$$

$$\text{kilo} \quad (=10^3) \text{ k}$$

$$\text{mega} \quad (=10^6) \text{ M}$$

$$\text{giga} \quad (=10^9) \text{ G}$$

$$\text{tera} \quad (=10^{12}) \text{ T}$$

(2) *The use of double prefixes should be avoided when single prefixes are available.*

$$\text{Not: } \text{m}\mu\text{s}, \quad \text{but: } \text{ns (nanosecond)}$$

$$\text{Not: } \text{kMW}, \quad \text{but: } \text{GW (gigawatt)}$$

$$\text{Not: } \mu\mu\text{F}, \quad \text{but: } \text{pF (picofarad)}$$

(3) *When a prefix is placed before the symbol of a unit, the combination of prefix and symbol should be considered as one new symbol, which can be squared or cubed without using brackets.*

EXAMPLES:

$$\text{cm}^2, \quad \text{mA}^2, \quad \text{s}^2$$

REMARK: cm^2 always means $(0.01 \text{ m})^2$ and never 0.01 m^2 .

Mathematical Operations. (1) *Multiplication of two units may be indicated in one of the following ways:*

$$\text{newton meter: } \text{Nm} \quad \text{N m} \quad \text{N} \cdot \text{m}$$

(2) *Division of one unit by another unit may be indicated in one of the following ways:*

$$\text{meter per second: } \frac{\text{m}}{\text{s}} \quad \text{m/s} \quad \text{m s}^{-1}$$

or by any other way of writing the product of m and s^{-1} . Not more than one solidus should be used.

EXAMPLES:

$$\text{Not: } \text{cm/s/s},$$

$$\text{but: } \text{cm/s}^2 = \text{cm s}^{-2}$$

$$\text{Not: } 1 \text{ poise} = 1 \text{ g/s/cm},$$

$$\text{but: } 1 \text{ poise} = 1 \text{ g/s} \cdot \text{cm} = 1 \text{ g s}^{-1} \text{ cm}^{-1}$$

$$\text{Not: } \text{J}^\circ\text{K/mol},$$

$$\text{but: } \text{J}^\circ\text{K mol} = \text{J}^\circ\text{K}^{-1} \text{ mol}^{-1}$$

Numbers and Figures. (1) *Numbers should be printed in upright type.*

(2) *Division of one number by another number may be indicated in the following ways:*

$$\frac{136}{273.15} \quad 136/273.15$$

or by writing it as the product of numerator and the inverse power of the denominator. In such cases, the number under the inverse power should always be placed between brackets.

REMARK: When the solidus is used and when there is any doubt where the numerator starts or the denominator ends, brackets should be used, as in the case of physical quantities.

(3) *To facilitate the reading of large numbers, the figures may be grouped in groups of three, but no comma should be used, since European convention uses the comma as a decimal point.*

EXAMPLE:

$$2\,573\,421\,736.01$$

Symbols for Chemical Elements, Nuclides, and Particles. (1) *Symbols for chemical elements* should be written in *roman* (upright) type. The symbol is not followed by a full stop.

EXAMPLES:

Ca C H He

(2) A nuclide is specified by the chemical symbol and the mass number, which should appear as a left superscript, e.g., ^{14}N . The atomic number may be shown too as a left subscript, e.g., ${}_7^{14}\text{N}$, if needed. The right superscript position may be used to indicate a state of ionization, e.g., Ca^{2+} , OH^- , or a state of excitation, e.g., $^{110}\text{Ag}^{\text{m}}$, $^4\text{He}^*$. The right subscript position is used to indicate the number of atoms of the specified nuclide or chemical element in a molecule, e.g., H_2SO_4 .

(3) Symbols for particles and quanta

neutron n

triton t

leptons e (electron), ν (neutrino), μ (muon)

mesons π (pion), K, η

baryons Λ , Σ , Ξ , Ω

proton p

α -particle α

deuteron d

photon γ

The charge of particles may be indicated by adding the superscript +, −, or 0.

EXAMPLES:

π^+ , π^- , η^0 , p^+ , p^- , e^+ , e^-

If in connection with the symbols p and e no charge is indicated, these symbols should refer to the positive proton and the negative electron respectively. The tilde above the symbol of a particle is often used to indicate the antiparticle of that particle (e.g., $\bar{\nu}$ for antineutrino).

Quantum States. (1) A symbol indicating the quantum state of a *system* such as an atom should be printed in capital roman (upright) type. The right subscript indicates the total angular momentum quantum number, and the left superscript indicates the multiplicity.

EXAMPLE:

$^2\text{P}_{3/2}$ (J = $\frac{3}{2}$, multiplicity: 2)

(2) A symbol indicating the quantum state of a single *particle* such as an electron should be printed in lower-case roman (upright) type. The right subscript may be used to indicate the total angular momentum quantum number of the particle in the case of j-j coupling.

EXAMPLE:

$p_{3/2}$ (electron state)

(3) The letter symbols corresponding to the angular momentum quantum number should be:

0 S, s 4 G, g 8 L, l
1 P, p 5 H, h 9 M, m

2 D, d 6 I, i 10 N, n

3 F, f 7 K, k 11 O, o

Nomenclature. (1) *Use of the word specific.* The word "specific" in English names for physical quantities should be restricted to the meaning "divided by mass."

EXAMPLES:

Specific volume volume/mass

Specific energy energy/mass

Specific heat capacity heat capacity/mass

(2) *Notation for covariant character of coupling:*

S Scalar coupling A Axial vector coupling

V Vector coupling P Pseudoscalar coupling

T Tensor coupling

(3) *Abbreviated notation for a nuclear reaction.* The meaning of the symbolic expression indicating a nuclear reaction should be the following:

$$\begin{array}{ccc} \text{Initial} & \left(\begin{array}{cc} \text{incoming} & \text{outgoing} \\ \text{particle} & \text{particle(s)} \\ \text{or} & \text{or} \\ \text{quantum} & \text{quanta} \end{array} \right) & \text{Final} \\ \text{nuclide} & & \text{nuclide} \end{array}$$

EXAMPLES:

$^{14}\text{N}(\alpha, p)^{17}\text{O}$ $^{59}\text{Co}(n, \gamma)^{60}\text{Co}$

$^{23}\text{Na}(\gamma, 3n)^{20}\text{Na}$ $^{31}\text{P}(\gamma, pn)^{29}\text{Si}$

(4) *Character of transitions.* Multipolarity of transition:

• Electric or magnetic	monopole	E0 or M0
" "	dipole	E1 or M1
" "	quadrupole	E2 or M2
" "	octupole	E3 or M3
" "	2 ⁿ pole	En or Mn

(5) *Nuclide.* A species of atoms, with specified atomic number and mass number should be indicated by the word *nuclide*, not by the word *isotope*.

Different nuclides having the same atomic number should be described as *isotopes*.

Different nuclides having the same mass number should be described as *isobars*.

Recommended Symbols for Physical Quantities.

REMARK: (1) Where several symbols are given for one quantity, and no special indication is made, they have equal weight.

(2) Only symbols are given for units in the tables below. All symbols are given in the mksA system of units. Units having special names in this system will be found listed separately on p. 702, together with their international symbols.

(3) Decimal multiples and submultiples of units are not explicitly mentioned in the tables; this does not mean, however, that they are not recommended.

Table of Symbols for Physical Quantities

Quantity	Symbol	International Symbol for Unit
SPACE AND TIME		
length	l	m
breadth	b	m
height	h	m
radius	r	m
diameter: $d = 2r$	d	m
path: $L = \int ds$	L, s	m
area	A, S	m ²
volume	V, v	m ³
plane angle	$\alpha, \beta, \gamma, \theta, \vartheta, \phi$	rad
solid angle	ω, Ω	sr
wave length	λ	m
wave number: $\sigma = 1/\lambda$	σ	m ⁻¹
circular wave number: $k = 2\pi/\lambda$	k	m ⁻¹
time	t	s
period	T	s
frequency: $\nu = 1/T$	ν, f	Hz
angular frequency: $\omega = 2\pi\nu$	ω	rad/s*
velocity: $v = ds/dt$	c, u, v	m/s
angular velocity: $\omega = d\phi/dt$	ω	rad/s
acceleration: $a = dv/dt$	a	m/s ²
angular acceleration: $\alpha = d\omega/dt$	α	rad/s ²
gravitational acceleration	g	m/s ²
standard gravitational acceleration	g_n	m/s ²
relative velocity: v/c	β	...
MECHANICS		
mass	m	kg
density: $\rho = m/V$	ρ	kg/m ³
reduced mass	μ, μ_r	kg
momentum: $p = mv$	p, p	kg·m/s
moment of inertia: $I = \int r^2 dm$	I, J	kg·m ²
force	F, f	$N \left(= \frac{\text{kg} \cdot \text{m}}{\text{s}^2} \right)$
weight	G, W	N
moment of force	M, M	N·m
pressure	p	N/m ²
normal stress	σ	N/m ²
shear stress	τ	N/m ²
gravitational constant: $F(r) = Gm_1m_2/r^2$	G	N·m ² /kg ²
modulus of elasticity, Young's modulus: $\sigma = E\Delta l/l$	E	N/m ²
shear modulus: $\tau = Gtg\gamma$	G	N/m ²
compressibility: $\kappa = -(1/V)dV/dp$	κ	m ² /N
bulk modulus: $K = 1/\kappa$	K	N/m ²
viscosity	η	N·s/m ²
kinematic viscosity: $\nu = \eta/\rho$	ν	m ² /s ²
friction coefficient	f	...
surface tension	γ, σ	N/m
energy	E, U	$J \left(= \frac{\text{kg} \cdot \text{m}^2}{\text{s}^2} \right)$
potential energy	V, E_p	J
kinetic energy	T, E_k	J
work	W, A	J
power	P	W (= J/s)
efficiency	η	...
Hamiltonian function	H	J
Lagrangian function	L	J
relative density	d	...

* The international bodies give s⁻¹ as the unit for angular frequency.

Quantity	Symbol	International Symbol for Unit
MOLECULAR PHYSICS		
number of molecules	N	
number density of molecules: $n = N/V$	n	m^{-3}
Avogadro's constant	$N_0, (L)$	mol^{-1}
molecular mass	m	kg
molecular velocity vector with components	$\mathbf{c}, (c_x, c_y, c_z)$	m/s
	$\mathbf{u}, (u_x, u_y, u_z)$	m/s
molecular position vector with components	$\mathbf{r}, (x, y, z)$	m
molecular momentum vector with components	$\mathbf{P}, (p_x, p_y, p_z)$	$\text{kg} \cdot \text{m/s}$
average velocity	$\mathbf{c}_0, \mathbf{u}_0, \bar{c}, \bar{u}$	m/s
most probable speed	\bar{c}, \bar{u}	m/s
mean free path	l	m
molecular attraction energy	ε	J
interaction energy between molecules i and j	ϕ_{ij}, V_{ij}	J
velocity distribution function: $n = \int f \, dc_x dc_y dc_z$	$f(c)$...
generalized coordinate	q	...
generalized momentum	p	...
volume in γ phase space	Ω	...
Boltzmann's constant	k	J/K
$1/kT$ in exponential functions	β	J^{-1}
gas constant per mole	R	$\text{J/mol} \cdot \text{K}$
partition function	Q, Z	...
diffusion coefficient	D	m^2/s
thermal diffusion coefficient	D_T	m^2/s
thermal diffusion ratio	k_T	...
thermal diffusion factor	α_T	...
characteristic temperature	Θ	K
Debye temperature: $\Theta_D = h\nu_D/k$	Θ_D	K
Einstein temperature: $\Theta_E = h\nu_E/k$	Θ_E	K
rotational temperature: $\Theta_r = h^2/8\pi^2Ik$	Θ_r	K
vibrational temperature: $\Theta_v = h\nu/k$	Θ_v	K
THERMODYNAMICS		
quantity of heat	Q	J
work	W, A	J
temperature	$t, (\theta)$	$^\circ\text{K}$
thermodynamic temperature	$T, (t)$	$^\circ\text{K}$
entropy	S	J/K
internal energy	U	J
Helmholtz function, free energy: $F = U - TS$	F	J
enthalpy: $H = U + pV$	H	J
Gibbs function: $G = U + pV - TS$	G	J
linear expansion coefficient	α	$^\circ\text{K}^{-1}$
cubic expansion coefficient	γ	$^\circ\text{K}^{-1}$
thermal conductivity	λ	$\text{W/m} \cdot \text{K}$
specific heat capacity	c_p, c_v	$\text{J/kg} \cdot \text{K}$
molar heat capacity	C_p, C_v	$\text{J/mol} \cdot \text{K}$
Joule-Thomson coefficient	μ	$^\circ\text{K} \cdot \text{m}^2/\text{N}$
ratio of specific heats	k, γ	...
ELECTRICITY AND MAGNETISM		
quantity of electricity	Q	$\text{C} (= \text{A} \cdot \text{s})$
charge density	ρ	C/m^3
surface charge density	σ	C/m^2
electric potential	V, Φ	$\text{V} (= \text{W/A})$
electric field	\mathbf{E}, E	$\text{N/C}, \text{V/m}$
electric displacement	\mathbf{D}, D	C/m^2
capacitance	C	$\text{F} (= \text{C/V})$
permittivity: $\varepsilon = D/E$	ε	F/m
permittivity of vacuum	ε_0	F/m
relative permittivity: $\varepsilon_r = \varepsilon/\varepsilon_0$	ε_r	...

Quantity	Symbol	International Symbol for Unit
dielectric polarization: $\mathbf{D} = \epsilon_0 \mathbf{E} + \mathbf{P}$	\mathbf{P}, P	C/m ²
electric susceptibility	χ_e	...
polarizability	α, γ	C · m ² /V
electric dipole moment	\mathbf{p}, p	C · m
electric current	I	A
electric current density	\mathbf{J}, J	A/m ²
magnetic field	\mathbf{H}, H	A/m
magnetic induction	\mathbf{B}, B	T (= Wb/m ²)
magnetic flux	Φ	Wb (= V · sec)
permeability: $\mu = B/H$	μ	H/m
permeability of vacuum	μ_0	H/m
relative permeability: $\mu_r = \mu/\mu_0$	μ_r	...
magnetization: $\mathbf{B} = \mu_0(\mathbf{H} + \mathbf{M})$	\mathbf{M}, M	A/m
magnetic susceptibility	χ_m	...
electromagnetic moment	μ, μ_e, m, m	A · m ²
magnetic polarization: $\mathbf{B} = \mu_0 \mathbf{H} + \mathbf{J}$	\mathbf{J}	Wb/m ²
magnetic dipole moment	\mathbf{j}, J	Wb · m
resistance	R	Ω (= V/A)
reactance	X	Ω
impedance: $Z = R + iX$	Z	Ω
admittance: $Y = 1/Z = G + iB$	Y	Ω^{-1}
conductance	G	Ω^{-1}
susceptance	B	Ω^{-1}
resistivity	ρ	$\Omega \cdot m$
conductivity: $1/\rho$	γ, σ	($\Omega \cdot m$) ⁻¹
self-inductance	L	H (= V · s/A)
mutual inductance	M, L_{12}	H
phase number	m	...
loss angle	δ	rad
number of turns	N	...
power	P	W
Poynting vector	\mathbf{S}, S	W/m ²
vector potential	\mathbf{A}	Wb/m

LIGHT, RADIATION

quantity of light	$Q(Q_v)$	lm · s
luminous flux	$\Phi(\Phi_v)$	lm
luminous intensity	$I(I_v)$	cd
illuminance	$E(E_v)$	lx (= lm/m ²)
luminance	$L, (L_v)$	cd/m ²
luminous emittance	M	lm · m ²
radiant energy	$Q, W, (Q_e)$	J
radiant flux	$\Phi, (P, \Phi_e)$	W
radiant intensity	$I, (I_e)$	W/sr
irradiance	$E, (E_e)$	W/m ²
radiance	$L, (L_e)$	W/sr · m ²
radiant emittance	$M, (M_e)$	W/m ²
absorptance	$\alpha(\lambda)$...
reflectance	$\rho(\lambda)$...
transmittance	$\tau(\lambda)$...
linear attenuation coefficient	$\mu(\lambda)$	m ⁻¹
linear absorption coefficient	$a(\lambda)$	m ⁻¹
refractive index	n	...
Stefan-Boltzmann constant: $\sigma = T^4/M$	σ	W/m ² · °K ⁴
luminous efficacy: Φ_v/Φ_e	K	lm/W
luminous efficiency: K/K_{\max}	V	...

ACOUSTICS

velocity of sound	c	m/sec
sound energy flux	P	W
reflection factor	ρ	...
acoustic absorption factor: $1 - \rho$	$\alpha, (\alpha_a)$...

Quantity	Symbol	International Symbol for Unit
transmission factor	τ	...
dissipation factor: $\alpha = \tau$	δ	...
loudness level	$L_N, (\Delta)$	phon
reverberation time	T	s
specific acoustic impedance	$Z_n, (W)$	$N \cdot s/m^3$
acoustic impedance	$Z_a, (Z)$	$N \cdot s/m^5$
mechanical impedance	$Z_m, (\omega)$	$N \cdot s/m$

ATOMIC AND NUCLEAR PHYSICS

atomic number, proton number	Z	...
mass number	A	...
neutron number: $N = A - Z$	N	...
elementary charge	e	C
electron mass	m, m_e	kg
proton mass	m_p	kg
neutron mass	m_n	kg
meson mass	m_π, m_μ	kg
atomic mass	$m_a, m(X)$	kg
(unified) atomic mass constant: $m_u = m_a(^{12}\text{C})/12$	m_u	u
magnetic moment of atom or nucleus	μ	$A \cdot m^2$
magnetic moment of proton	μ_p	$A \cdot m^2$
magnetic moment of neutron	μ_n	$A \cdot m^2$
magnetic moment of electron	μ_e	$A \cdot m^2$
Bohr magneton	μ_B	$A \cdot m^2$
Planck constant $\left(\frac{h}{2\pi} = \hbar\right)$	h	J · s
principal quantum number	n, n_1	...
orbital angular momentum quantum number	L, l_1	...
spin quantum number	S, s_1	...
total angular momentum quantum number	J, j_1	...
magnetic quantum number	M, m_1	...
nuclear spin quantum number	I	...
hyperfine quantum number	F	...
rotational quantum number	J, K	...
vibrational quantum number	v	...
quadrupole moment	Q	m^2
Rydberg constant	R_∞	m^{-1}
Bohr radius: $a_0 = 4\pi\epsilon_0\hbar^2/m_e e^2$	a_0	m
fine structure constant: $\alpha = e^2/4\pi\epsilon_0\hbar c$	α	...
mass excess: $m_a - Am_u$	Δ	kg
mass defect	B	kg
packing fraction: Δ/Am_u	f	...
nuclear radius: $R = R_0 A^{1/3}$	R	m
nuclear magneton	μ_N	$A \cdot m^2$
g -factor of nucleus: $\mu = gI\mu_N$	g	...
gyromagnetic ratio: $\gamma = \mu/I\hbar$	γ	$A \cdot m^2/J \cdot s$
Larmor (angular) frequency	ω_L	rad/s
cyclotron (angular) frequency	ω_c	rad/s
level width	Γ	J
mean life	τ	s
reaction energy	Q	J
cross section	σ	m^2
macroscopic cross section	Σ	m^2
impact parameter	b	m
scattering angle	$\vartheta, \theta, \varphi$	rad
particle flux density	Φ	$s^{-1} \cdot m^{-2}$
particle fluence	Φ	m^{-2}
energy flux density	ψ	W/m^2
energy fluence	F	J/m^2
internal conversion coefficient	α	...
reaction energy	Q	J
half-life	$T_{1/2}$	s

Quantity	Symbol	International Symbol for Unit
decay constant, disintegration constant	λ	s^{-1}
activity	A	s^{-1}
Compton wavelength: $\lambda_c = h/mc$	λ_c	m
electron radius: $r_e = e^2/mc^2$	r_e	m
linear attenuation coefficient	μ, μ_1	m^{-1}
atomic attenuation coefficient	μ_a	m^2
mass attenuation coefficient	μ_m	m^2/kg
linear stopping power	S, S_1	J/m
atomic stopping power	S_a	$J \cdot m^2$
linear range	R, R_1	m
recombination coefficient	α	m^3/s
linear ionization by a particle	N_{i1}	m^{-1}
total ionization by a particle	N	...
number of neutrons per fission	ν	...
number of produced neutrons per absorption	η	...
absorbed dose	D	J/kg (rad)
linear energy transfer	L	J/m

CHEMICAL PHYSICS

amount of substance	n, ν	mol
molar mass of substance B	M_B	kg/mol
molar concentration of substance B	c_B	mol/m ³
mole fraction of substance B	x_B	...
molar internal energy	$U_m, (E_m)$	J/mol
mass fraction of substance B	w_B	...
molality of solution	m	mol/kg
chemical potential	μ	J/mol
activity of component B	λ_B	...
relative activity	a_B	...
activity coefficient (molar fraction, molality, molarity scales)	f_B, γ_B, γ_B	...
osmotic pressure	Π	N/m ²
osmotic coefficient	g, ϕ	...
stoichiometric number of molecule B	ν_B	...
affinity	A	J/mol
equilibrium constant	K_p	(N/m ²)
charge number of ion	z	...
Faraday constant	F	C/mol
ionic strength	I	mol/kg
fugacity of component B	f_B	N/m ²
electrolytic conductivity	σ, κ, γ	$\Omega^{-1} \cdot m^{-1}$
transport number	t	...
degree of dissociation	α	...

Recommended Mathematical Symbols:

GENERAL SYMBOLS

equal to	$=$
not equal to	\neq, \neq
identically equal to	\equiv
corresponds to	\sim, \sim
approximately equal to	\approx
proportional to	\propto, \propto
approaches	\rightarrow, \rightarrow
larger than	$>, >$
smaller than	$<, <$
much larger than	\gg
much smaller than	\ll
larger than or equal to	\geq, \geq, \geq
smaller than or equal to	\leq, \leq, \leq
plus	$+$
minus	$-$

Quantity	Symbol	International Symbol for Unit
plus or minus	\pm	
a raised to the power n	a^n	
magnitude of a	$ a $	
square root of a	$\sqrt{a}, \sqrt[3]{a}, a^{1/2}$	
mean value of a	$\bar{a}, \langle a \rangle, \langle a \rangle_{av}$	
factorial p	$p!$	
binomial coefficient: $n!/p!(n-p)!$	$\binom{n}{p}$	

LETTER SYMBOLS AND LETTER EXPRESSIONS FOR MATHEMATICAL OPERATIONS

These should be written in roman (or upright) type	
exponential of x	$\exp x, e^x$
base of natural logarithms	e
logarithm to the base a of x	$\log_a x$
natural logarithm of x	$\ln x$
common logarithm of x	$\lg x, \log x$
summation	Σ
product	Π
finite increase of x	Δx
variation of x	δx
total differential of x	dx
function of x	$f(x), f(x)$
limit of $f(x)$	$\lim f(x)$

TRIGONOMETRIC FUNCTIONS

sine of x	$\sin x$
cosine of x	$\cos x$
tangent of x	$\tan x, \operatorname{tg} x$
cotangent of x	$\cot x, \operatorname{ctg} x$
secant of x	$\sec x$
cosecant of x	$\operatorname{cosec} x$

REMARKS: (a) It is recommended to use for the *inverse circular functions* the symbolic expressions for the corresponding circular function preceded by the letters: arc.

EXAMPLES:

$\arcsin x, \arccos x, \arctan x$ or $\operatorname{arctg} x$, etc.

Sometimes the notation $\sin^{-1} x, \tan^{-1} x$, etc., is used.

(b) It is recommended to use for the *hyperbolic functions* the symbolic expressions for the corresponding hyperbolic function, followed by the letter: h.

EXAMPLES:

$\sinh x, \cosh x, \tanh x$ or $\operatorname{tgh} x$, etc.

(c) It is recommended to use for the *inverse hyperbolic functions* the symbolic expression for the corresponding hyperbolic function preceded by the letters: ar.

$\operatorname{arsinh} x, \operatorname{arcosh} x$, etc.

COMPLEX QUANTITIES

imaginary unit ($i^2 = -1$)	i, j
real part of z	$\operatorname{Re} z, z'$
imaginary part of z	$\operatorname{Im} z, z''$
modulus of z	$ z $
argument of z : $z = z \exp i\phi$	$\arg z, \varphi$
complex conjugate of z , conjugate of z	z^*

REMARK: Sometimes the notation \bar{z} is used for the complex conjugate of z .

VECTOR CALCULUS (SEE ALSO P. 695)

absolute value	$ A , A$
differential vector operator	$\partial/\partial r, \nabla$
gradient	$\operatorname{grad} \varphi, \nabla \varphi$
divergence	$\operatorname{div} A, \nabla \cdot A$
curl	$\operatorname{curl} A, \operatorname{rot} A, \nabla \times A$
Laplacian	$\Delta \varphi, \nabla^2 \varphi$
d'Alembertian	$\square \varphi$

MATRIX CALCULUS

transpose of matrix A	$\tilde{A}_{ij} = A_{ji}, \tilde{A}$
complex conjugate of A	$(A^*)_{ij} = (A_{ij})^*, A^*$
Hermitian conjugate of A	$(A^\dagger)_{ij} = A_{ji}^*, A^\dagger$

International Symbols for Units. Unit systems.

(1) A *coherent system of units* is a system based on a certain set of "basic units" from which all "derived units" are obtained by multiplication or division without introducing numerical factors. In addition there are "dimensionless units," in particular the radian, symbol: rad, for plane angle and the steradian, symbol: sr, for solid angle.

(2) The *cgs system* or *cm-g-s system* is a coherent system of units based on *three basic units* for the three basic quantities length, mass and time:

centimeter	cm
gram	g
second	s

In the field of *mechanics* the following units of this system have special names and symbols, which have been approved by the General Conference on Weights and Measures:

l, b, h	centimeter	cm
t	second	s
m	gram	g
f, ν	hertz ($=s^{-1}$)	Hz
F	dyne ($=g \cdot cm/s^2$)	dyn
E, U, W, A	erg ($=g \cdot cm^2/s^2$)	erg
p	microbar ($=dyn/cm^2$)	μ bar
η	poise ($=dyn \cdot s/cm^2$)	P

In the field of *electricity and magnetism* several variants of the cgs unit system have been developed, in particular the *electrostatic cgs system* and *electromagnetic cgs system*. Special names and symbols for some of the units of the second system are:

H	oersted ($=cm^1 \cdot g^1 \cdot s^{-1}$)	Oe
B	gauss ($=cm^1 \cdot g^1 \cdot s^{-1}$)	G
Φ	maxwell ($=cm \cdot g^1 \cdot s^{-1}$)	Mx

(3) The *mksA system* or m-kg-s-A system is a coherent system of units for mechanics, electricity and magnetism, based on *four basic units* for the four basic quantities length, mass, time, and electric current intensity:

meter	m
kilogram	kg
second	s
ampere	A

REMARK: The system based on these four units was given the name *Giorgi system* by the International Electrotechnical Committee in 1958. The mechanical system, which is based on the first three units only, has the name *mks system*.

The following units of the mksA system have special names and symbols, which have been approved by the General Conference on Weights and Measures:

l, b, h	meter	m
t	second	s
m	kilogram	kg
ν, f	hertz ($=s^{-1}$)	Hz
F	newton ($=kg \cdot m/s^2$)	N
E	joule ($=kg \cdot m^2/s^2$)	J
P	watt ($=J/s$)	W
I	ampere	A
Q	coulomb ($=A \cdot s$)	C
V	volt ($=W/A$)	V
C	farad ($=C/V$)	F
R	ohm ($=V/A$)	Ω
L	henry ($=V \cdot s/A$)	H
Φ	weber ($=V \cdot s$)	Wb
B	tesla ($=Wb/m^2$)	T

(4) In the field of *thermodynamics* one introduces an additional basic unit, corresponding to the basic quantity: *thermodynamic temperature*, the unit being the degree Kelvin, symbol: $^{\circ}K$.

When the *customary temperature* is used, defined by $t = T - T_0$, where $T_0 = 273.15^{\circ}K$, this is usually expressed in degrees Celsius, symbol: $^{\circ}C$. For *temperature interval* the name degree, symbol: deg, is often used, the indications "Kelvin" or "Celsius," indicating the zero-point of the temperature scale used, being irrelevant in this case.

(5) In the field of *photometry* one introduces an additional basic unit, corresponding to the basic quantity: *luminous intensity*, this unit being the candela, symbol: cd. Special names for units in this field are:

I	candela	cd
Φ	lumen	lm
E	lux ($=lm/m^2$)	lx

(6) *The International System of Units*. For the system based on the six basic units:

meter	m	ampere	A
kilogram	kg	degree Kelvin	$^{\circ}K$
second	s	candela	cd

The name *International System of Units* has been recommended by the Conférence Générale des Poids et Mesures in 1960:

(7) In the field of *chemical and molecular physics*, in addition to the basic quantities defined above, *amount of substance* is also treated as a basic quantity. The basic recommended basic unit is the mole, symbol: mol. The mole is defined as the amount of substance, which contains the same number of elementary units (e.g. atoms, molecules, ions, electrons, or groups of such entities corresponding to a stated formula), as there are atoms in exactly 12 grams of the pure carbon nuclide ^{12}C .

INCOHERENT UNITS

l	ångström	Å
σ	barn ($=10^{-28} cm^2$)	b
V	liter	l
t, τ, T_1	minute	min
t, τ, T_1	hour	h
t, τ, T_1	day	d
t, τ, T_1	year	a
p	atmosphere	atm
P	kilowatt-hour	kWh
Q	calorie	cal
Q	kilocalorie	kcal
E, Q	electronvolt	eV
m	ton ($=1000 kg$)	t
m_A, m	(unified) atomic mass unit	u
p	bar ($=10^6 dyn/cm^2$)	bar

REMARK: The (unified) atomic mass unit is defined as $\frac{1}{12}$ th of the mass of an atom of the ^{12}C nuclide.

SYMMETRY. See CONSERVATION LAWS AND SYMMETRY.

SYNCHROTRONS

The term synchrotron has come to mean "a ring shaped device for accelerating charged particles, e.g., electrons, protons, deuterons, to relativistic energies by the repeated passage of the particles, at essentially constant radius, through a time-varying electric field which alternates in direction at a fixed or variable frequency." Special examples are: (1) weak focusing synchrotrons; (2) alternating-gradient synchrotrons (AGS); (3) fixed-field alternating-gradient synchrotrons (FFAG), or azimuthally varying field synchrotrons (AVF). All these machines have evolved from the early accelerators invented by E. O. Lawrence (cyclotron—1930), D. W. Kerst (betatron—1940), the synchronous acceleration principle discovered by E. M. McMillan and V. Veksler (1945), and the alternating-gradient strong focusing principle of Christofilos (1950), and Livingston, Courant and Snyder (1952).

There are basically six components or functions which a synchrotron must provide: (1) a source of particles, e.g., electrons or protons with energy and direction suitable for injection; (2) a vacuum chamber; (3) a magnet to bend particles in a circle; (4) focusing of particles; (5) acceleration of particles; (6) ejection of particles.

Ion Source. Electrons or ions to be accelerated are generally produced in an external device by a hot cathode or a gaseous discharge and then, after being electromagnetically focused into a narrow pencil, they are accelerated up to several tens of MeV before injection into the synchrotron magnet gap. The optimum injector energy depends upon a number of factors, e.g., minimum magnet field

strength at which the magnetic field shape will produce satisfactory focusing, space charge limitations, design of the radio-frequency acceleration system, and "inflection" problems associated with bending the particles into orbit. Generally speaking, a fairly high injector energy is preferred since most of the above problems are eased as the injector energy increases. Very close tolerances must be placed on the energy and angular spread of the injected beam; otherwise the particles will strike the walls of the vacuum chamber after only a few turns. Injector accelerators generally in use are: (1) Cockroft Walton (500 kV); (2) Van de Graaff (3 to 5 MeV); (3) linear accelerators (15 to 50 MeV).

Vacuum Chamber. Since particles are scattered by collision with air molecules, it is necessary to provide a good vacuum over the entire region traversed by the particles while they are undergoing acceleration. The most critical period is when the particles are at low velocity, for then the Rutherford nuclear scattering and small angle atomic scattering are most probable. A vacuum of 10^{-6} mm of Hg is generally quite sufficient to reduce gas scattering losses to negligible proportions. In order that the vacuum chamber walls should not interfere with the magnetic field, or its space and time derivatives, it is customary to employ either insulating walls, e.g., ceramic, epoxy fiber glass, or laminated metal structures made vacuum tight by an outer vacuum envelope of rubber or epoxy fiber glass.

Bending. A particle of rest mass m_0 , charge $Z \cdot e$, and kinetic energy T , moving in a direction perpendicular to a magnetic field of B gauss, will move in a circle of radius R given by:

$$B \cdot R = \frac{1}{9.15Z} (T^2 + 2TE_0)^{1/2} \quad \begin{matrix} \text{(kilogauss,} \\ \text{feet, MeV)} \end{matrix}$$

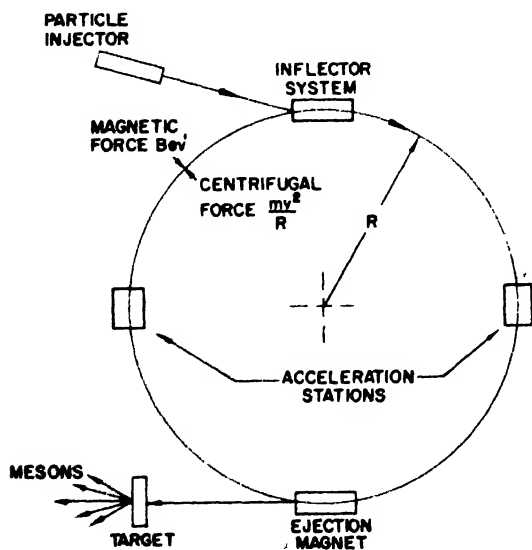

FIG. 1. Synchrotron.

where $E_0 = m_0c^2$, the rest energy of the particle. From this equation it can be seen that as the particle energy is increased from a very low initial energy to the final energy of several thousand MeV, the product $B \cdot R$ must increase manifold. If B is held constant in time during the acceleration cycle and if the space average of B is also relatively constant, then R must increase with energy thus leading to the need for a very large radial aperture over which the field must be maintained. This is the case with cyclotrons. The radial aperture can be drastically reduced in either of two ways: (1) time modulate (e.g., pulse) the magnetic field so that it increases from a few tens or hundreds of gauss at ion injection time up to 10 to 20 kilogauss at which field the maximum particle energy is reached; (2) shape the magnetic field such that it increases sharply with increasing radius. The latter approach, while seemingly obvious, actually requires a very sophisticated angular and radial variation of the field in order to retain focusing in the direction parallel to the magnetic field. (It has been done by L. H. Thomas, 1938; Ohkawa, 1955; Kolomenskij, Petukhov,

and Rabinovitch, 1955; Symon, 1955.) Accelerators based on this time-independent but spatially varying field are generally referred to as FFAG or Spiral Sector Ring Accelerators. Their major utility appears to be in the field of high ion currents, which they can achieve by virtue of their non-pulsed character, but they appear to be practicable up to only a few thousand MeV of energy since they still require considerable radial aperture. By far the most widely exploited type of synchrotron is that first mentioned, i.e., the time-varying magnetic field, which holds the particles at an essentially constant radius while gaining energy. This technique, which leads to a simpler magnet design and a minimum of weight, will be described in detail in the remainder of this article.

Focusing. A magnetic field which is perfectly uniform over the entire circular path of the particle and over the radial aperture leads to stable motion only for radial displacements of the particle. Particles displaced parallel to B (i.e., out of the orbit plane) are not refocused back on to the original circle and are quickly lost to the chamber walls. This can be readily understood by noting that motion parallel to B generates no $eV \times B$ force, and therefore such motion persists until the particle strikes the chamber walls. However, by deliberately introducing curved lines of force, it is possible to produce $eV \times B$ forces whose net effect results in restoring forces for all displacements from the ideal circular orbit. Subsequent to the pioneer cyclotron and

betatron work, in which a simple *decrease* of magnetic field with *increasing* radius leads to a weak-focusing action, there has evolved a wide variety of field shapes which have much stronger focusing action. All these strong-focusing fields are characterized by rapid spatial changes in the field strength, reversal of sign of field gradients and even of the field itself. The most widely employed alternating gradient scheme is one in which a magnet sector that focuses *radially*, but defocuses *axially*, is followed by a sector which has the reverse property, i.e., *defocuses* radially and focuses axially. The net effect is strong focusing in *both* directions. There is a close analogy between alternating-gradient synchrotron focusing and an alternating series of convergent and divergent optical lenses whose net action is focusing. As a result of this arrangement of magnetic lenses, it is possible to use larger field gradients than in the weak-focusing case and thereby to achieve very strong focusing action. For example, an alternating-gradient 35 000-MeV accelerator, 560 feet in diameter, requires a vacuum chamber with a cross section of only 2.7×6 inches, whereas a weak-focusing, constant-gradient synchrotron would require at least ten times more aperture for equivalent performance.

Acceleration. The increase in particle energy actually takes place when the circling charged particles pass through electric fields spaced around the circumference of the magnet. These fields must be time varying since a complete, repetitive traversal of a static field leads to zero energy

TABLE 1. SOME TYPICAL SYNCHROTRONS

	Princeton-Pennsylvania Accelerator, Princeton, N.J.	Brookhaven National Laboratory, Upton, L. I.	Joint Institute for Nuclear Research, Dubna, USSR	CEA Electron Accelerator, Cambridge, Mass.
1. Focusing scheme	Weak	Strong	Weak	Strong
2. Particle	Protons	Protons	Protons	Electrons

gain. The usual arrangement is one in which the acceleration electrodes are excited by a sinusoidal voltage whose frequency is a harmonic (one to several hundred) of the particle rotation frequency and whose amplitude is such that particles can gain sufficient energy to match the rising magnetic field. Because of the principle of synchronous phase stability, discovered by McMillan and Veksler, particles with a wide spread in phase angle relative to the radio frequency are captured in stable "buckets" in phase space and are accelerated at just the correct rate, on the average, to stay in the middle of the vacuum chamber. Of course, the frequency of the accelerating field must be steadily and precisely increased as the particle rotation frequency increases. In some weak-focusing synchrotrons, this is one of the most difficult engineering tasks.

Ejection. When the particles have been accelerated to full energy, they are caused either to run into an internal target or they are ejected by one of several schemes which usually involve exciting strong radial betatron oscillations with the last oscillation carrying the particles into an ejection magnet which deflects the beam clear of the synchrotron magnet structure.

In Table I are listed the important parameters of several typical existing synchrotrons. The

principles discussed above for the alternating-gradient, strong-focusing accelerator (AGS) are believed to be capable of extension to almost any energy, limited only by financial considerations. There are now serious proposals before the Government agencies for synchrotrons with energy in the 200 to 1000 BeV range. The latter would cost around 700 million dollars and would be 4452 meters in diameter.

T

TELEGRAPHY

Modern telegraphy has evolved into a science of such electronic sophistication that it bears practically no resemblance to its technological genesis. New developments arise so rapidly that today's theory quite literally becomes tomorrow's practice. Also, the scope of telegraphy has been broadened to include many new record services, such as data, facsimile, telemetry, etc.

Basically, most written telegraphed intelligence begins with a teleprinter, a typewriter-like piece of equipment, which performs the functions of coding, sending, receiving and decoding telegraph signals using only make-and-break transmission. Synchronism is achieved by the "start-stop" method by which a "start" pulse releases corresponding parts of the printing and transmitting units simultaneously. These parts operate in unison until the "stop" pulse arrests their motion and holds them until the succeeding start pulse arrives. The whole operation takes only 154 msec, which is approximately 390 characters or 65 words per minute. Faster speeds up to 100 words per minute are used where it is required.

A network of 15 high-speed switching centers, located throughout the country, cuts the manual handling of telegrams to one simple typing operation at the point of origin. The originating operators easily route outgoing telegrams to other switching centers by transmitting two "call letters" at the beginning of messages. An "electrical brain" in the connecting switching center is activated by these call letters and selects the proper circuit, automatically speeding the telegram to its destination.

Incoming telegrams, addressed to a point within the switching area, are received on a telegraph device known as a printer-perforator, which simultaneously types the telegram on the top of the tape while perforating code combinations in the tape. As each telegram arrives, a switching clerk presses a button marked with the name of its destination, thus connecting the message with a wire and automatically sending the telegram to its destination.

Western Union uses carrier systems, which multiply by many times the capacity of its wire and radio beam circuits, to make available the channels required to interconnect its country-wide network of switching centers. The fundamental principle of the carrier system is that

alternating or pulsating currents of a number of different frequencies are passed over a circuit, each frequency serving as a transmission channel. Individual transmitting devices control the application of the current at each frequency, and at the receiving end, the complex current composed of all the various frequencies is passed through electrical filters. Each filter segregates a particular frequency, which in turn is transmitted to appropriate receiving devices. In this way, a large number of individual channels may be obtained from one electrical circuit.

Since 1946 Western Union has been transmitting over a radio beam system linking New York and Philadelphia. The beam system was extended to Washington, D.C., and Pittsburgh two years later, and extensions to other cities followed. As originally designed, this network can transmit 2000 telegrams simultaneously in both directions.

The new 7500-mile transcontinental microwave system is now providing greatly enlarged capacity accommodating all known forms of communications at extremely high speeds and in large volume. It will handle sophisticated computer "talk," high-speed data and facsimile, and voice—as well as conventional telegraph. Engineered to allow for 100 per cent expansion, the network will be capable of beaming 12,000 simultaneous, two-way messages.

Towers in the radio beam system are spaced at intervals of 30 to 50 miles in "line of sight," as microwaves travel in a straight line. The towers are necessary to redirect the beam at these distances to compensate for the curvature of the earth. Super high-frequency radio waves are transmitted by directional beams from tower to tower where unattended stations automatically amplify and instantaneously relay the signals.

Atmospheric static is not a problem in the microwave region, and radio beam transmission is not bothered by electrical disturbances. Concentration of the available power into a sharply defined directional beam makes it possible to utilize the same radio-frequency channel over and over again.

The carrier system used on the radio beam furnishes 600 independent voice circuits and occupies the frequency range from 60 kc to 2.54 Mc. Each voice band provides a working transmission path extending from 200 to 3600 cycles, sufficient to accommodate 20 narrow-band

(150-cycle spacing) telegraph carrier channels or ten 180-baud data channels.

By supplementary equipment arrangement, the system may be modified to provide frequency bands roughly equivalent to 2, 4, 8 or 12 voice bands for use in broadband switching applications.

Telegraph facsimile has been so simplified in design and operation that today it is growing in importance as a means of fast, efficient communication. At the sending point, matter to be transmitted is placed upon the revolving drum of a facsimile machine and scanned by a finely focused beam of light. The minute gradations of current intensity thus produced are amplified and transmitted to the distant end.

There they are amplified again and passed to a small stylus which rests lightly on a sheet of chemically prepared conducting paper ("Teledeltos") upon a revolving drum in exact synchronism with the drum at the sending point. As the stylus moves longitudinally along the revolving drum, the current passes through the paper with the result that the chemically treated surface of the paper is burned off leaving a black mark. Thus, exact reproductions of the transmitted matter are recorded and are at once available for use without the necessity of developing a film and making a photographic print.

A substantial portion of Western Union's business is derived from the private wire systems it designs, installs and leases to governmental and industrial customers. One of these, the AUTODIN system for the Department of Defense, is the world's most versatile and largest digital data communications network. AUTODIN is currently capable of transmitting 16 million punch cards daily, or the equivalent of 320 million words. Because it incorporates entirely new concepts and techniques in automated electronic switching, data can be exchanged from all kinds of transmission equipment—punch card machines, magnetic tape devices and teleprinters. This system is now being expanded to double its present size.

A smaller but somewhat similar system is the Advanced Record System for the General Services Administration scheduled for operation early in 1965. Initially, this computer-controlled network will handle $2\frac{1}{2}$ million messages yearly with a handling capability of 7 million annually.

Cross-references: COMPUTERS, MICROWAVE TRANSMISSION, TELEMETRY.

TELEMETRY

The terms telemetry and telemetering imply both distance and measurement, but beyond this there is not universal agreement regarding the use and meaning of the terms. The American Standards Association defines telemetering as: "The measurement with the aid of intermediate means which permit the measurement to be interpreted at a distance from the primary detector." The distance involved may be anywhere

from a few inches in the case of certain test projectiles to many millions of miles in the case of space probes to other planets. Other terms such as data transmission system or data link are frequently used. A distinction in terminology is sometimes made between the transmission of a measurement for observation and interpretation and the transmission of a measurement to directly govern a controlling action. In modern applications, the quantity transmitted may not be a measurement at all, but the result of some complex calculation based on numerous measurements over a time interval.

The dominant transmission means for telemetry has been electrical, and a few applications were already reported during the first half of the nineteenth century. During the latter half of that century, applications included regular transmission of meteorological and other measurements. During the early part of the twentieth century, there were extensive applications of telemetry in connection with the Panama Canal followed by applications in many other areas such as electrical power and pipeline distribution systems. Soon after 1930, telemetry through the transmission medium of radio links was in use for meteorological measurements from small unmanned balloons. Soon after 1940, the first radio telemetering systems for testing aircraft were being designed and used. This occurred in response to the need for more complete and reliable measurement during experimental flights of high-performance military aircraft than could be provided by onboard recorders and pilot's observations. By 1945 radio telemetry was being used for measurements in the then small rockets. Subsequently, the development of advanced radio telemetering systems has been spurred by the well-known rapid development of the field of rocket-propelled vehicles. Recently, telemetry has seen rapidly increasing application in geophysical and biomedical research.

It is sometimes convenient to divide telemetry applications into two areas which might be called operational and test. By operational we mean the application of telemetry as a permanent part of some system in which case the telemeter must be compatible with the rest of the system in such aspects as cost, reliability, and maintainability. By test we mean the temporary application of telemetry to obtain test information during the developmental phase of some system in which case the telemeter need not be completely compatible with the rest of the system.

Telemetry systems for industrial purposes tend to fall more under the operational area and formed the majority of applications before 1940. Industrial telemetering systems have been frequently characterized by modest requirements for speed of response and accuracy which fall well within the physical limitations of the transmission link (frequently wire circuits) and are therefore accomplished by rather straightforward and uncomplicated signal handling methods. On the other hand, these applications have been characterized by demanding requirements for low first cost and

high reliability during long periods of unattended operation. Geophysical (including oceanographic) applications often have similar requirements. Industrial telemetry is well exemplified by the many thousands of telemeters in constant use by the electrical power industry throughout the world to measure electrical quantities and plant conditions.

The majority of aerospace telemetry during the last twenty years has been in the test area. Because of the destructive nature of tests and/or the difficulty in repeating them and because of the marginal nature of many of the systems being tested, aerospace telemetry has been characterized by demanding requirements for speed of response, accuracy, and number of channels which are frequently not well within the physical limitations of the radio transmission link. This together with severe weight and space restrictions and difficult environmental conditions for equipment operation has resulted in a field of telemetry activity more or less separate from the industrial area. Much attention has been given to the statistical efficiency of signal handling in the presence of random errors of various kinds and to the specialized hardware techniques needed to satisfy space, weight, power supply, and environmental conditions. The recent advent of long-lived satellites and space probes, including many systems whose only mission is telemetered measurements, has greatly emphasized telemetry reliability considerations.

The deeper understanding of the nature of measurement and information that has occurred during the last two decades by application of statistical methods has had its effect on the telemetering field. In the beginning, the design and classification of telemetering systems tended to be in terms of the physical quantity measured, the physical quantities used for transmission and interpretation, and the transducers for conversion between these physical quantities, i.e., in terms of the hardware. Terms such as current, voltage, frequency, ratio, phase, impulse, etc., were and are used to describe some systems. Multiplexing (the transmission of many measurements over the same channel) was either frequency division (assignment of a frequency band to each measurement, non-overlapping with those of the others) or time division (assignment of a periodic time interval to each measurement, non-overlapping with those of the others).

The statistical systems point of view in telemetry is concerned with *what* is done to the signal rather than *how* it is accomplished physically. From this point of view a telemetering system may do any or all of the following in logical sequence: (1) make a measurement; (2) abstract from the measurement in the form of a signal those characteristics which are needed for the eventual interpretation or decision; (3) store this signal; (4) code (modulate) this signal to give it greater immunity to the errors in the transmission link; (5) receive the signal; (6) store the signal; (7) decode (demodulate) the received signal to best preserve those characteristics which

are needed for interpretation and decision; (8) store the result. A measurement is said to have been made on a system if after the measurement, the uncertainty regarding the quantitative state of the system is less than the uncertainty existing before the measurement. Uncertainty in the sense of information theory has an exact quantitative measure in terms of the probability distributions involved and can be replaced by a cost index when a cost criterion is available. Similarly, a measurement is said to have been telemetered when there is a reduction in uncertainty or cost on the basis of the data produced by the telemetering system.

Current radio telemetering systems use many methods of modulation in various combinations. These include amplitude, phase, frequency, pulse amplitude, pulse position, pulse duration, pulse frequency, and pulse code. Multiplexing is sometimes accomplished by more general orthogonal methods than frequency- and time-division. With the advent of solid-state active circuit components and, most recently, of microelectronic techniques there has been a revolution in telemetry hardware. The practicability of complex circuits made possible by solid-state components, the use of digital computers for data handling, and developments in improved coding and demodulation methods have brought about considerable use of pulse-code modulation telemetering systems during the last decade.

Cross-reference: MEASUREMENT, PRINCIPLES OF.

TEMPERATURE AND THERMOMETRY

Temperature is the degree of hotness or coldness as measured on a definite scale; it is that property of an object which determines the direction of heat flow when the object is placed in contact with another. The concept serves as a measure of the average kinetic energy of the molecules of an object due to heat agitation. Human sensory organs can furnish an approximate indication of air temperature or of the temperature of an object. However, this indication can be strongly affected by factors such as moisture in the air or the heat conductivity of the object. Thermometry is the measurement of temperature and utilizes changes in some property of an object as an indicator. Changes in pressure, volume, length,

electrical resistance, and electrical potential have all been used in thermometers.

Temperature Scales. Many different scales have been used in measuring temperatures. The most common of them are Celsius or centigrade, Fahrenheit, Réaumur, Kelvin or centigrade absolute, and Rankine. Symbols used for the units on these scales are °C, °F, °R, °K, and °R, respectively. The Kelvin scale is noteworthy because it is essentially the true thermodynamic scale. The scales are all based on one primary reference point, which represents the temperature at which sharp change occurs. This temperature is assigned a number and serves as a starting point. A second reference point determines the size of the degree. All of these scales use the same primary reference point called the "ice-point". This is the temperature at which pure macroscopic ice crystals are at equilibrium with pure, liquid water under air saturated with moisture and at standard atmospheric pressure (1.01325 bar or 1.013 250 dynes/cm²). For the various scales this point is assigned numerical values as follows: 0°C, 32°F, 0°Réaumur, 491.7°Rankine, and 273.15°K. The value of 273.15°K is set so as to bring the scale as close as possible to the true thermodynamic scale. It is based on the use of 273.16°K for the triple point of water as an international standard (see STATES OF MATTER). The secondary point is that temperature at which the vapor pressure of pure water is equal to standard atmospheric pressure. The temperature interval between the primary and secondary points is divided into degrees, and the number of them between the two points is 100 Celsius degrees, 180 Fahrenheit degrees, 80 Réaumur degrees, 180 Rankine degrees, and 100 Kelvin degrees. When working above the secondary point or below the primary point, an attempt is made to keep the degrees the same size as those between the fixed points. The Fahrenheit and Rankine degrees are five-ninths as big as the Kelvin and Celsius or centigrade degrees.

Conversion from Scale to Scale. The conversion of a temperature reading from one scale to another requires remembering that the degrees are not always the same size and that the zero mark does not represent the same temperature on the different scales. Methods or formulas for the conversions can then be derived.

To convert a reading from degrees centigrade to degrees Fahrenheit, multiply by 9/5 and then add 32.

To convert a reading from Fahrenheit to centigrade, subtract 32 and multiply by 5/9.

To convert a reading from centigrade to Kelvin, add 273.15.

To convert a reading from Kelvin to centigrade, subtract 273.15.

To convert a reading from Fahrenheit to Rankine, add 459.7.

To convert a reading from Rankine to Fahrenheit, subtract 459.7.

To convert a reading from centigrade to Réaumur, multiply by 4/5.

To convert a reading from Réaumur to centigrade multiply by 5/4.

Similar formulas can be derived for conversions not shown above, or the calculation can be made in steps, using the conversions above to go from one scale to another until the desired reading is obtained. If a large number of readings must be converted, the use of a table such as may be found in handbooks is preferable both from the standpoint of avoiding mistakes and as a time saving device.

Reference Temperatures. By international agreement, a series of reference temperatures has been established to assure uniformity in measurements when using various types of precision thermometers. This is necessary because of lack of uniformity in changes in volume or length or electrical properties with respect to changes in temperature. The international temperature scale between -190 and +660°C is based on the resistance of a standard platinum resistance thermometer using the following formula for resistance at a temperature t :

Below 0°C:

$$R_t = R_0[1 + At + Bt^2 + C(t - 100)t^3]$$

Above 0°C:

$$R_t = R_0(1 + At + Bt^2)$$

where A , B and C are arbitrary constants. Starting at 660°C and up to the gold point, a platinum-platinum rhodium thermocouple is used, and above that, an optical pyrometer (see THERMOELECTRICITY and PYROMETRY, OPTICAL). Basic reference points include the boiling point of oxygen (-182.970°C), the triple point for water (+273.16°K), the boiling point of sulfur (+444.600°C), the melting point of silver (+960.8°C), and the melting point of gold (+1063.0°C).

Utilization of Temperature Scales. The centigrade or Celsius scale is very widely used for scientific studies, and most thermometers for exacting work are calibrated in this scale. It was invented in 1742 by Anders Celsius and, though the name centigrade is still widely accepted, the preferred name is Celsius. The Fahrenheit scale is used in every day life in the United States and England, and is the usual scale for engineering and medical practice in those countries. The Réaumur scale is in limited use in France, Germany, and Russia. The Rankine Scale is used in some engineering work, particularly where an absolute scale is needed for such things as the calculation of the theoretical efficiency of engines. The Kelvin scale was originated by Lord Kelvin and was based on a consideration of the second law of thermodynamics. This leads to a temperature scale with the zero point at the temperature at which all the thermal motion of the atoms stops. By using this as the zero point or absolute zero and another reference point to determine the size of the degrees, a scale can be defined. The Comité Consultative of the International Committee of Weights and Measures selected 273.16°K as the value for the triple point for water. This set the ice-point at 273.15°K.

Thermodynamic Scale. Thermodynamically speaking, the thermal efficiency E of an engine is equal to the work W derived from the engine divided by the heat supplied to the engine Q_2 . If Q_1 is the heat exhausted from the engine,

$$E = (W/Q_2) = (Q_2 - Q_1)/Q_2 = 1 - (Q_1/Q_2)$$

where W , Q_1 , and Q_2 are all in the same units. A Carnot engine is a theoretical one in which all the heat is supplied at a single high temperature and the heat output is rejected at a single temperature. The cycle consists of two adiabatics and two isothermals (see CARNOT CYCLES AND CARNOT ENGINES.) Here the ratio Q_1/Q_2 must depend only on the two temperatures and on nothing else. The Kelvin temperatures are then defined by the relation

$$\frac{Q_1}{Q_2} = \frac{T_1}{T_2}$$

where Q_1/Q_2 is the ratio of the heats rejected and absorbed, and T_1/T_2 is the ratio of the Kelvin temperatures of the reservoir and the source. If one starts with a given size for the degree, then the equation completely defines a thermodynamic temperature scale.

A series of Carnot engines can be postulated so that the first engine absorbs heat Q from a source, does work W , and rejects a smaller amount of heat at a lower temperature. The second engine absorbs all the heat rejected by the first one, does work and rejects a still smaller amount of heat which is absorbed by a third engine, etc. The temperature at which each successive engine rejects its heat becomes smaller and smaller, and in the limit this becomes zero so that an engine is reached which rejects no heat at a temperature which is absolute zero. A reservoir at absolute zero cannot have heat rejected to it by a Carnot engine operating between a higher temperature reservoir and the one at absolute zero. This can be used as the definition of absolute zero. Absolute zero is then such a temperature that a reservoir at that temperature cannot have heat rejected to it by a Carnot engine which uses a heat source at some higher temperature.

Thermometry. The measurement of temperature can be accomplished by many devices with varying degrees of accuracy or convenience. Among the instruments most frequently used are those based on (1) expansion of a solid, a liquid, or a gas; (2) change of pressure in a gas or vapor kept at a constant volume; (3) the thermoelectric effect; (4) changes in electrical resistance; and (5) changes in the character of thermal radiation.

The familiar mercury-in-glass thermometer utilizes the expansion of mercury which expands much more rapidly than does its glass container. For a wider temperature range, alcohol, usually colored for easier visibility, can be substituted. Maximum thermometers, such as the clinical thermometer, have a very narrow constriction just above the bulb so that if the temperature goes down, the mercury column breaks at the constriction leaving the column in the tube above the

constriction to indicate the highest temperature reached. A minimum thermometer can be built by including a small rider or index. As the liquid in the thermometer contracts, the rider is pulled towards the bulb, its end staying just at the surface of the liquid. If temperature goes up, the liquid flows past the index, leaving it to indicate the lowest temperature reached.

Gases are used as the working fluid in two types of thermometer. One holds the pressure constant, and the change in volume provides the temperature indication. The other is usually more convenient to use. In it the volume of the gas is held constant, and changes of pressure indicate temperature changes. Gases which are close to ideal gases are used, and corrections can be made for nonideal behavior so that the readings follow the absolute thermodynamic scale. This constant volume type has been adopted as the practical standard for the measurement of temperature.

A bimetallic strip can be made from small strips of two different metals welded or riveted together side by side. If the two have different coefficients of expansion, changes in temperature will cause the bimetallic strip to bend as one metal expands more than the other. This can be used to move a pointer over a scale. By using the motion of one end of the strip to open and close electrical contacts, a thermostat results for electrically controlling devices such as furnaces, ovens, or air conditioning units.

The thermoelectric effect can be used to measure temperature because the difference in potential created at a junction varies as a smooth function of temperature. The junction or sensor can be made very small and with low heat capacity so that such a thermocouple can be used for the precise indication of rapid changes in temperature.

Resistance thermometers require a wire or strip of metal and a circuit for determining changes in the resistance of the strip or wire as temperature changes.

An optical pyrometer measures the thermal radiation from a hot object over a narrow wavelength region and uses this radiation as a measure of temperature. Measurements are made by comparing brightness with that of a standard or by using photoelectric detectors. Such pyrometers can be used for temperatures far above those which can be measured by other methods (see PYROMETRY, OPTICAL). Radiation pyrometers measure the total thermal radiation and use this as an indication of temperature. They tend to be less accurate than optical pyrometers.

Each type of thermometer has its own advantages and disadvantages, and the choice of which to use must be made on the basis of the requirements of each particular application.

THEORETICAL PHYSICS

A division of physics into the two broad categories of theoretical and experimental physics is very common. Both, of course, share the general aim of physics to describe and correlate the results of past experiments, to predict the numerical results of experiments yet to be performed, and to develop concepts and methods which enable one to encompass many diverse and related phenomena into a single coherent description. The questions which one can ask of a physical theory are therefore of a "how" type, for example, "How long will it take a falling stone to reach the ground?" or "How many degrees would the temperature of the water in this pail drop if I were to leave it on this block of ice for one hour?" Questions of a "why" type such as, "Why does the stone fall toward the earth when I release it?" are presumed to be of the type which cannot legitimately be asked of physics. In general terms, the role of theoretical physics is the development of concepts which can be represented by mathematical symbols and then manipulated by using the wide variety of mathematical tools available; hence, the principal characteristic of theoretical physics is the importance of mathematics in its formulation and methods. The intermediate stages of a typical calculation generally cannot be checked at every step by a corresponding experiment. The value of a particular theory can therefore only be justified by how well the final results predicted by it agree with experiment. Occasionally it has been found that two quite different theories will agree equally well with experiment; then the choice between them has been made on another basis, usually by favoring the simpler one.

Theoretical physics as a career in itself became important only in this century. Pioneers in the development of physics such as Galileo and Newton did notable experiments in addition to the creation of useful mathematical methods. Much of the initial theoretical effort was devoted to MECHANICS and culminated in the development of Lagrange's and Hamilton's equations of motion. An important synthesis occurred later when it was found to be possible to write Maxwell's equations for electromagnetism in the same Hamiltonian form which had been devised for mechanics. Consequences of the rise of the atomic theory of matter were such subjects as KINETIC THEORY and STATISTICAL MECHANICS in which the bulk properties of materials are calculated as averages of mechanical and electrical characteristics of a large number of atomic and molecular particles. QUANTUM MECHANICS, as a method of dealing with the wave properties of matter, was developed during the first thirty years or so of this century and made it possible to calculate individual atomic properties which had become

measurable as a result of greatly improved experimental techniques. The older forms of mechanics, which had been so successful up to then, survived as a limiting case of the newer quantum mechanics. At about this same time, theoretical physics became a recognized specialty and the number of theoretical physicists has subsequently greatly increased. Present day theoretical physicists work both on the solution of specific problems of practical interest by known methods, and on the development of new theories appropriate to the description of the large amount of newly obtained experimental data. For convenience, theoretical physics can be divided into subject matter fields such as mechanics, electrodynamics, statistical mechanics, quantum mechanics, quantum field theory, and relativity. Another convenient subdivision is into macroscopic and microscopic theories. A macroscopic theory generally deals solely with relations among the measured properties of matter in bulk such as its heat capacity and electrical conductivity; thermodynamics is such a theory. In a microscopic theory, on the other hand, one tries to account for these large scale features in a more "fundamental" way by obtaining them from atomic properties. Related to this approach is the unsolved question of whether the fundamental numerical constants of nature, such as the electric charge and the mass of the electron, must be left entirely to experimental determination or may some day be calculable directly from a suitable general theory.

Experimental physics and theoretical physics are constantly influencing each other. Theory is strongly dependent upon experiment because the results of experiments provide the motivation to develop a new theory or to try to combine several existing theories into a more complete and general one. In turn, theory makes important contributions by suggesting new experiments which can serve to check various aspects of the theory or by predicting a previously unknown effect. Much of the effort of theoretical physicists is devoted to the extension and investigation of their theories in an attempt to predict such new effects. If these are confirmed by experiment, they increase one's confidence in the theory. Experimental results which differ from theoretical predictions show the necessity of improving the theory—sometimes the disagreement is so great that radical revisions are necessary. A few experiments have become known as "crucial" experiments because they have provided an unambiguous comparison between the basic foundations of an accepted theory and experiment. A famous example is the MICHELSON-MORLEY EXPERIMENT on the dependence of the speed of light upon the direction of motion of the earth in its orbit. The flat disagreement between the results of this experiment and the predictions of the then current theory led Einstein to make his searching reexaminations of the fundamental concepts of space and time which resulted in his development of the theory of relativity. It is common practice for experimenters to try to find empirical

formulas which will describe their results, and it is a constant challenge to theory to account for and to derive these formulas. Such formulas are common in SPECTROSCOPY, and their simplicity as compared to the complexity of the measurements inspired many efforts to calculate them; the first success of this kind was attained by Bohr in his quantum theory of the spectrum of hydrogen. Occasionally, use has been made of "thought experiments." As the name implies, these are not actually performed but are imagined and then analyzed in detail. For example, Heisenberg considered the use of a microscope as an instrument for measuring the position of a particle, paying particular attention to the effect of the interaction between the particle and the light which scatters the incident light into the microscope thus enabling the particle to be located. Considerations such as these were extensively used in the early development of quantum mechanics for the formulation of the "uncertainty principle" which is a statement of the inherent limitations on the accuracy of simultaneous measurements of related variables such as position and momentum.

Generally, theoretical physicists spend much of their time trying to solve specific problems. Often a problem arises from the need to fit the results of a given experiment into the established theory. Many problems are devised by the theoretical physicist himself, since experience has shown that progress in theory has rarely been accomplished by means of a single brilliant stroke of exceptional generalization, but rather by the slower process of solving bits at a time. It is only later that these various problems and their solutions can be combined into a more general problem in which the previous ones are now special cases of the new formulation. A particular situation may require new methods, and it is only by handling simplified cases at first that one can obtain enough experience and facility to enable the more complex case of ultimate interest to be finally solved. Accordingly, much of the training of physicists involves solving specific problems which are incorporated into textbooks. An important attribute of a competent theoretical physicist, which is much more profound than being able to solve an already existing problem, is the ability to formulate useful and significant problems, i.e., the ability to ask the right questions.

Virtually all theoretical problems involve a high degree of idealization. Quite often, the experimental situation involves very many variables and specific details of widely varying importance. The initial task of the theoretical physicist is to try to estimate which variables are of principal significance so that he can then decide which can be safely neglected in his analysis. For example, a volume of interest may often be regarded as so large that its boundaries can be assumed to be infinitely far away so that their effects are negligible. In essence, then, what is sought is a reasonable and tractable approximation that is a fairly good substitute for the

actual state of affairs. Arguments involving whatever properties of symmetry the system may have often play an important role in the approach to a problem. If, for example, it can be assumed that the distribution of mass in the earth depends only on the distance from the center and not on the particular direction in which one proceeds from the center, then the gravitational attraction of the earth will also not depend on direction but will involve only the distance from the center. Using this consequence of the geometrical symmetry, it is possible to simplify the problem by restricting one's attention only to those possible solutions which do not depend on any angle or direction. Although there exist a wide variety of formal methods of solution which have been devised through the years, one should also recognize how great the importance of experience has been as is shown by the many successful uses of intuition, hunches, and inspired guesses. Sometimes, one is somewhat inexplicably led to try a particular solution, which, upon test, turns out to be either the correct solution to the problem or so near to it that it is a relatively simple matter to adjust the trial solution to make it correct. At times, these trials are based on the knowledge that a uniqueness theorem exists, i.e., it has been shown previously that a particular equation has only one possible solution. One can then be confident that, no matter how devious the means may have been by which the solution was obtained, it is the only possible one and it is not necessary to spend one's time considering other possibilities. Many problems can be solved by using a general solution which has been found for a more general problem and then reducing this solution to the specific one needed at the moment by making it satisfy the appropriate conditions at the boundaries of regions concerned; these boundary conditions then suffice to determine specific numerical values of parameters which appear in the mathematical form of the general solution and which previously had to be left undetermined.

Somewhat related to the value of intuition is the extensive use which is made of analogies in the solution of certain problems. It is often quite surprising how many diverse subjects and topics can be described by exactly the same form of mathematical equations; this is an example of the unifying role of theoretical physics. From a practical point of view, methods and concepts which have proved useful in one field can then be transferred bodily over into another, without, in many cases, it being necessary to change the terminology. As an example, many problems in coupled vibrating mechanical systems have been successfully treated by using methods which were originally developed to cope with coupled oscillating electrical circuits. Similarly, the motion of electrons through the lattice of ions in a metal can be related to the propagation of waves along a chain of masses connected by springs.

From a purely mathematical point of view, the student of theoretical physics soon finds that very many problems cannot be solved exactly

in terms of simple or well-known mathematical functions. Although, in principle, these problems could all be solved by numerical methods, it is often of more interest and value to have a mathematically simple form for the solution. Consequently, the use of approximations is very extensive. This often consists of an expansion of a solution in a power series and of keeping only the first few terms since the others are of negligible magnitude. Sometimes only a knowledge of the order of magnitude of a quantity is sufficient, and this can be estimated quite well in spite of the impossibility of obtaining an exact solution, which in itself may be so complicated as to obscure the underlying features. In recent years, the development and availability of high-speed computers has been of great value for theory. The computers enable one to obtain numerical solutions of problems which previously were not solved because conventional numerical methods would simply take too long. Computer solutions have also proved useful in indicating the direction which should be taken by analytical methods and in suggesting appropriate types of approximations.

THERMIONICS

Thermionics is the science of the emission of electricity from solids induced by high temperature.

While thermionic emission was undoubtedly observed long ago in the discharge of electrified particles near heated solids and considerably studied in the last half of the nineteenth century,

not much progress in understanding it was made because fundamental concepts of the electric current were lacking. At the beginning of the present century the existence of the electron was established, and since then thermionics progressed rapidly both in theory and applications so that now it is basic to many large industries. As a measure of its growth, there are now in use probably two billion thermionic tubes in a host of different applications, and the basic theory of thermionics is largely worked out.

Among the early workers with currents from hot electrodes were Hittorf (1869-1883) and Goldstein (1885), both drawing quite large currents, and Elster and Geitel (1882-1889) who worked with very small currents, both positive and negative, in their research on the phenomenon. Edison (1883) in his work on the incandescent lamp discovered current emitted from the hot carbon filament and proposed a use for it in a patent granted to him. This emission became known as the "Edison Effect." None of these men, however, knew what they had, supposing that they dealt with ions such as occur in electrolysis or gas discharges. It was not until 1897-1899 that the work of J. J. Thomson showed that the negative carriers of cathode rays were a new species of particle with mass about 1700 times smaller than that of the hydrogen ion. This was the electron. Drude (1900) suggested that electrons rather than metallic ions are the carriers of current in metals, and Thomson proposed that they are also the negative charges emitted by hot metals. O. W. Richardson made a study on this basis (1901) and derived two forms of the "Richardson equation" relating the emitted current density i to the absolute temperature T of the metal and a property of the metal expressed by the letter b . The equations are

$$i = A_1 T^{1/2} \exp\left(-\frac{b_1}{T}\right) \quad (1)$$

and

$$i = A_2 T^2 \exp\left(-\frac{b_2}{T}\right) \quad (2)$$

A_1 and A_2 are arbitrary constants, $\exp(z)$ stands for the base of natural logarithms $e = 2.718$ raised to the exponent or power z , and b relates to the work required to remove an electron from the inside to the outside of the metal surface. The derivation of Eq. (1) was made using classical mechanics and the Maxwell-Boltzmann distribution of energies, later shown not to hold for free electrons within a metal. Equation (2) was based on the experimental fact that the electrons do not share in the specific heat of the metal. The formula even now retains essentially its original form [Eq. (2)], with expressions for the constants given in terms of known quantities. Richardson verified the form of his formula by careful experimental tests. Neither he nor subsequent workers could discriminate between the two forms, but the second is thought to be on a better theoretical basis. Richardson also introduced the term "thermionic."

W. Schottky (1919) and S. Dushman (1923) derived an expression for the constant A_2 in Eq. (2):

$$A = \frac{2T_1 k^2 m e}{h^3} = 60.2 \text{ amperes/cm}^2 \text{ deg}^2 \quad (3)$$

Here k is Boltzmann's constant, m is the mass and e the charge of the electron, and h is Planck's constant. Later derivations of the expression take into account the Sommerfeld (1928) theory of metallic conduction, the Pauli exclusion principle, and the spin of the electrons to yield a value of A of 120 amperes/cm² deg². The value of the exponent becomes

$$\frac{b}{T} = \frac{e\phi}{kT} + \frac{W_a - W_1}{kT} \quad (4)$$

Here ϕ is called the work function of the metal, usually expressed as a measured quantity in volts; W_a is the work of moving the electron out against the surface barrier, and W_1 is the energy the electron may have had inside the metal. There is in addition a factor introduced to account for the reflection r of electrons at the inner surface of the metal. The present form of the Richardson equation is then; according to Nordheim (1929).

$$i = A(1 - r) \exp\left(-\frac{e\phi}{kT}\right) \quad (5)$$

The exponential term of the expression has been amply verified over a large temperature range. The work function ϕ is known for a large number of metals. It tends to be larger for metals in which the atoms are packed closely together, smaller for open lattice metals, the range being about 1.5 to 6 volts. It is slightly higher on dense crystal faces than on open ones. The constant A may appear to vary by a large amount from its theoretical value of 120, in the range of 10 to 100 for pure metals. Actually, it is not that A is different but that ϕ varies with temperature. The pure metal that is most often used as a thermionic emitter where ruggedness and high voltage are involved is tungsten, because of its strength and high melting point. For it, the values of ϕ and apparent A are about 4.5 volt and 100 amperes/cm²deg². Molybdenum, tantalum and niobium are others used in special applications.

The thermionic properties of a metal surface are profoundly changed by thin films of foreign materials. This is the basis of the thoriated tungsten emitter used in small- and medium-size vacuum tubes by Langmuir and Rodgers in 1914. The filament is made of tungsten having a small additive of thorium. In the heat treatment, some of the thorium diffuses to the surface where it forms a quite stable deposit that is less than one atom deep. The work function of this surface is less than that of either thorium or tungsten, about 2.6 volts, and A is about 3 ampere/cm² deg². Where the tungsten filament is normally operated near 2700°K the thoriated tungsten yields a comparable emission current density

at 1800 to 2000°K, with a very considerable saving in heating power. The surface is less rugged than that of pure tungsten.

By far the larger number of vacuum tubes use the oxide-coated filament, described by Wehnelt (1904). On a metallic base that is usually a nickel alloy is deposited a relatively thick coating of the mixed oxides of barium, strontium and calcium. Certain activation processes yield a surface with work function ϕ in the region of 1 volt. In spite of the small and variable value of the factor A , in the range of .01, the low work function provides a surface of high emission so that it can be used at the temperature of near 1000°K, giving still higher thermal efficiency than the thoriated tungsten. The mechanism of electron emission from this surface is considerably different from that of the pure metal. The oxide layer is normally an insulator at room temperature that becomes a semi-conductor at the operating temperature. The oxides are partly dissociated so that there are metal atoms, particularly of barium, in the body of the layer and on its surface. The surface barium probably contributes to the low work function. The body barium is presumably ionized so that it contributes conduction electrons in the semi-conductor. At the metal-oxide interface, there is another low work function surface so that electrons can pass from the metal base into the oxide, to be available for emission at the outer surface. With this modified mechanism, the emission equation still essentially holds. The reason is largely that the Boltzmann factor $\exp\left(\frac{e\phi}{kT}\right)$

varies so rapidly with temperature that it renders other factors of little consequence experimentally.

So far it has been assumed that there is another electrode nearby with high enough positive voltage on it so that all of the emitted electrons are drawn to it. The current is then said to be saturated. In this condition, the current can still increase slowly with increasing voltage. The reason is that the strong electric field at the surface of the metal penetrates between the surface atoms and helps the electrons escape. The actual current then is increased above the saturation current by a factor $\exp 4.40 \left(\frac{F^{1/2}}{T}\right)$ determined

by Schottky in 1914, where F is the field strength in volts per centimeter, as verified with the refractory metals. With thoriated tungsten, the increase is more rapid than this, and with the oxide cathodes, the increase is so rapid that it is hard to say when saturation sets in.

At still higher surface fields, of the order 10 million volts/cm, another emission effect sets in, whereby the electrons are drawn out of even the cold metal. This is FIELD EMISSION, q.v.

At voltages below that required for saturation, the repulsion between the negatively charged electrons tends to limit the current. This is the space charge region, the condition in which most thermionic devices work. The current then is fairly insensitive to temperature and other conditions at the cathode so long as the anode voltage

is well below the saturation value. In this condition, the current can be controlled by grids and other means. The space charge limited current between a plane emitting cathode and an anode at the distance d from it and at voltage, V , each of area 1 cm^2 , is given fairly closely by the expression

$$i = 2.33 \times 10^{-6} V^{3/2} / d^2 \text{ amperes} \quad (6)$$

derived by Child (1911) and by Langmuir (1913). The equation is modified for a cylindrical structure, but the $V^{3/2}$ factor applies to any structure.

When the potential between emitter and plate is reversed so as to become retarding for electrons, the current is limited to the number of electrons with enough energy to overcome the retarding potential and is not limited by space charge. The current i_r is then related to the saturation current i_s by the expression

$$i_r = i_s \exp\left(-11600 \frac{V_r}{T}\right) \quad (7)$$

T being the temperature of the emitter and V_r the retarding potential. This may be written

$$\log i_r = -5030 \frac{V_r}{T} + \log i_s \quad (8)$$

Besides giving a means of determining the temperature of the emitter as shown by Germar (1925), the formula also is at the basis of electronic devices with logarithmic response.

The emission of positive ions from hot bodies seemed, before the existence of the electron was recognized, to be as important as the negative emission, and much work was devoted to it. It turned out eventually that it was not an important property of the body of the emitter but rather one of surface impurities. Richardson (1903-1914) showed that the positive ions given off by hot metals were ionized alkali atoms, and with a simple mass spectrometer he determined that they were mostly potassium coming originally from the glass envelope of the tube. Later studies have amply verified this finding, and the reason for it is now understood. A surface atom on a hot metal will be evaporated as a positive ion if the ionization potential of the atom is less than the work function of the metal, the metal then retaining the electron. This condition is satisfied with high work function metals as a base and with potassium, rubidium, cesium and possibly sodium as the impurity atoms.

There have been few practical applications of the positive ion emission beyond that of Kunsman (1927), but it has been useful in certain experimental researches such as those of Langmuir and Kingman (1925).

THERMODYNAMICS

Classical Thermodynamics is a theory which on the basis of four main laws and some ancillary assumptions deals with general limitations exhibited by the behavior of macroscopic systems. Phenomenologically it takes no cognizance of the atomic constitution of matter. All *mechanical* concepts such as kinetic energy or work are presupposed. Thermodynamics is motivated by the existence of dissipative mechanical systems. A *thermodynamic system* K may be thought of as a collection of bodies in bulk; when its condition is found to be unchanging in time (on a reasonable time scale) it is *in equilibrium*. It is then characterized by the values of a finite set of say n physical quantities, it being supposed that none of these is redundant. Such a set of quantities constitutes the *coordinates* of K , denoted by $x (=x_1, \dots, x_n)$. Any set of values of these is a *state* \mathfrak{S} of K . In virtue of these definitions, K is in a state only when it is in equilibrium. The passage of K from a state \mathfrak{S} to a state \mathfrak{S}' is a *transition* of K . A transition is *quasi-static* if in the course of it goes through a continuous sequence of states, and if the forces which do work on the system are just those which hold it in equilibrium. A transition is *reversible* if there exists a second transition which restores the initial state, the final condition of the surroundings of K being the same as the initial condition. Reversible transitions are assumed to be quasi-static.

An enclosure which is such that the equilibrium of a system contained within it can only be disturbed by mechanical means is *adiabatic*, otherwise it is *diathermic*. For instance, stirring, or the passage of an electric current, constitute "mechanical means." A system K_0 in an adiabatic enclosure is *adiabatically isolated* but this does not preclude mechanical interactions with the surroundings. Its transitions are then called *adiabatic*.

For the time being, the masses of all substances present will be supposed fixed, and to achieve simplicity it will be given that (1) there are no substances present whose properties depend on their previous histories; (2) capillary forces as well as long-range interactions are absent. Further it will be supposed that of the n coordinates of K just $n - 1$ have geometrical character (*deformation coordinates*, e.g., volumes of enclosures), so

that the work done by K in a quasi-static transition is

$$\int dW = \int_{k=1}^{n-1} P_k(x) dx_k \quad (1)$$

Such a system will be called a *standard system* ($n-1$ enclosures in diathermic contact, each containing a simple fluid, may serve as example, x_n being any one of the pressures).

The Zeroth Law. Suppose two systems $K_A(x)$ and $K_B(y)$ to be in mutual diathermic contact. Experience shows that the states \mathfrak{E}_A and \mathfrak{E}_B cannot be assigned arbitrarily, but that there exists a necessary relation of the form

$$f(x; y) \equiv f(x_1, \dots, x_n; y_1, \dots, y_m) = 0 \quad (2)$$

between them. If K_C is a third system, its diathermic equilibrium with K_B on the one hand, or with K_A on the other, is governed by conditions

$$g(y; z) = 0 \quad (3)$$

and

$$h(z; x) = 0 \quad (4)$$

respectively. That these three functions are not independent is expressed by the *Zeroth Law*: *If each of two systems is in equilibrium with a third system then they are in equilibrium with each other.* It follows that any two of Eqs. (2) through (4) imply the third, i.e., they must be equivalent to equations of the form

$$\xi(x) = \eta(y) = \zeta(z) \quad (5)$$

Thus with each system there is now associated a function, its *empirical temperature function*, such that two systems can be in equilibrium if and only if their *empirical temperatures* (i.e., the values of their empirical temperature functions) are equal. Write $t = \xi(x)$; so that one has the *equation of state* of K_A . Also, t may be introduced in place of any one of the x_k . Note that the empirical temperature is not uniquely determined since $t_A = t_B$ may be replaced by $\phi(t_A) = \phi(t_B)$ where the function ϕ is monotonic but otherwise arbitrary: one has a choice of *temperature scales*. For a system not in equilibrium temperature is not defined.

The First Law. It is obvious that one can do mechanical work upon a system (say by stirring) while its initial and final states are the same. (Nothing is being said about the surroundings!) In this sense mechanical energy is not conserved. One might however hope that it is conserved at least in a restricted class of transitions. That this is so is asserted by the *First Law*: *The work W_0 done by a system K_0 in an adiabatic transition depends on the terminal states alone.* Thus if $\mathfrak{E}'(x')$, $\mathfrak{E}''(x'')$ are the terminal states

$$W_0 = F(x'; x'')$$

If $\mathfrak{E}'''(x''')$ is a third state, and the previous transition proceeds via \mathfrak{E}''' , W_0 must not depend on x''' , i.e.,

$$F(x'; x''') + F(x'''; x'') \equiv F(x'; x'')$$

It follows that there must exist a function $U(x)$, defined to within an arbitrary additive constant, such that

$$F(x'; x'') = U(x') - U(x'') (= -\Delta U \text{ say})$$

$U(x)$ is the *internal energy function* of K . (To make sure that U is in fact defined for all states, one assumes that *some* adiabatic transition always exists between any pair of given states.) The energy of a compound standard system is the sum of the energies of its constituent standard systems. Further, U must be a monotonic function of t , and it is convenient to choose the scale of t such that $\partial U / \partial t > 0$.

When the transition from \mathfrak{E}' to \mathfrak{E}'' is adiabatic, $W_0 + \Delta U$ vanishes by definition of U . If the transition is not adiabatic and W is the work done by K , the quantity

$$\Delta U + W (= Q, \text{ say}) \quad (6)$$

will in general fail to vanish. Q is then called the *heat absorbed* by K . Every element of a quasi-static adiabatic transition is subject to $dQ = 0$, i.e., by Eqs. (1) and (6), to the differential equation

$$\sum_{k=1}^{n-1} \left(P_k(x) + \frac{\partial U(x)}{\partial x_k} \right) dx_k + \frac{\partial U}{\partial t} dt = 0 \quad (7)$$

The Second Law. Experiment shows that if \mathfrak{E}' and \mathfrak{E}'' are arbitrarily prescribed states, then it may be that no adiabatic transition from \mathfrak{E}' to \mathfrak{E}'' exists. When this is the case one says that \mathfrak{E}'' is *inaccessible* from \mathfrak{E}' , but \mathfrak{E}' is then accessible from \mathfrak{E}'' , as has been already assumed. The states may of course happen to be mutually accessible. The existence of states adiabatically inaccessible from a given state is asserted precisely by the *Second Law*: *In every neighbourhood of any state \mathfrak{E} of an adiabatically isolated system there are states inaccessible from \mathfrak{E} .* (This formulation of the Second Law is known as the *Principle of Carathéodory*.) *A fortiori* this law applies to quasi-static transitions, i.e., those which satisfy Eq. (7). It asserts there are states \mathfrak{E}'' near \mathfrak{E}' such that no functions $x_k(t)$ exist which satisfy Eq. (7) and whose values when $t = t''$ are just x_k'' , ($k = 1, \dots, n-1$). It is merely a mathematical problem (the Theorem of Carathéodory) to prove that this is the case if and only if there exist functions $\lambda(x)$ and $s(x)$, ($x_n \equiv t$) such that the left-hand member is identically equal to λds , where ds is the total differential of s . Thus, the Second Law entails that

$$dQ = dU + dW = \lambda ds \quad (8)$$

(dQ is of course not a total differential). s is called the *empirical entropy function* of K . It is not uniquely determined, since it may be replaced by any monotonic function of s . If two standard systems K_A and K_B in diathermic contact make up a compound system K_C , $dQ_C = dQ_A + dQ_B$, i.e., because of Eq. (8),

$$\lambda_A ds_A + \lambda_B ds_B = \lambda_C ds_C$$

By including s_A, s_B and the common empirical temperature t among the coordinates of K_C , one infers that

$$\lambda_A = T(t)\theta_A(s_A), \lambda_B = T(t)\theta_B(s_B),$$

$$\lambda_C = T(t)\theta(s_A, s_B)$$

The common function $T(t)$ is called the *absolute temperature function*, while

$$S_A(s_A) = \int \theta_A(s_A) ds_A$$

is the *metrical entropy* of K_A . The "element of heat" dQ of any standard system thus splits up into the product of a universal function of the empirical entropy and the total differential $dS(x)$ of the metrical entropy function:

$$T dS = dU + dW' \quad (9)$$

By multiplying T by a constant and dividing S by the same constant, T can be arranged to be positive.

If one now chooses $x_n = S$ and recalls that the $x_k (k < n)$ are freely adjustable, the Second Law would be violated if S were also adjustable at will (by means of non-static adiabatic transitions.) Taking continuity requirements into account, it follows that S can either never decrease or never increase. The single example of the sudden expansion of a real gas shows that it can never decrease. One has the *Principle of Increase of Entropy: The entropy of an adiabatically isolated system can never decrease.*

The Third Law. It is known from experiment that for given values of the deformation coordinates, the energy function has a lower bound U_0 . The question arises whether the entropy S has an analogous property. It is found in practice that the specific heats $\partial U / \partial T$ of all substances appear to go to zero at least linearly with T as $T \rightarrow 0$. This ensures that the function S goes to a finite limit S_0 as $T \rightarrow 0$. Experiment shows however further that as $T \rightarrow 0$, the derivatives of S with respect to the deformation coordinates also go to zero. In contrast with U_0 , S_0 has therefore the remarkable property that it is independent of the deformation coordinates. One thus arrives at the *Third Law: The entropy of any given system attains the same finite least value for every state of least energy.* One immediate consequence of this is that the so-called *classical ideal gas* (the product of whose volume V and pressure P is proportional to T , and whose energy is a function of T only) cannot exist in nature. Further, no system can have its absolute temperature reduced to zero. The Third Law is therefore a statement about the properties of functions, not of systems, at $T = 0$.

The practical applications of the theory just outlined divide themselves into two broad classes: (1) those which are based on the existence and properties of the functions U and S and some others related to them—all "thermodynamic identities" being merely the integrability condition for the total differentials of these functions;

and (2) those which are based on the Principle of Increase of Entropy: the entropy of the actual state of an adiabatically enclosed system being greater than that of any neighbouring "virtual" state.

The most important of the auxiliary functions just mentioned are the *Helmholtz Function*:

$$F = U - TS \quad (10)$$

the *Gibbs Function*:

$$G = U - TS + \sum_{k=1}^{n-1} P_k x_k \quad (11)$$

the *Enthalpy*:

$$H = U + \sum_{k=1}^{n-1} P_k x_k \quad (12)$$

sometimes called *thermodynamic potentials*. Then, e.g.,

$$dF = -S dT - dW$$

F therefore contains all available quantitative information about K , since

$$S = -\frac{\partial F}{\partial T}, \text{ and } P_k = \frac{\partial F}{\partial x_k} \quad (13)$$

The same is true of G for instance, since

$$S = -\frac{\partial G}{\partial T}, \text{ and } x_k = \frac{\partial G}{\partial P_k}$$

F and G are naturally taken as functions of x_1, \dots, x_{n-1}, T and of P_1, \dots, P_{n-1}, T , respectively. At times one speaks of F as the "Helmholtz free energy" and of G as the "Gibbs free energy." In an *isothermal* reversible transition, the amount W of work done by a system is equal not to the decrease of its energy U but to the decrease $-\Delta F$ of its (Helmholtz) free energy. In the presence of internal sources of irreversibility

$$W < -\Delta F$$

In considering physicochemical equilibria, that is to say, if one is interested in the internal constitution of a system in equilibrium when changes of phase and chemical reactions are admitted, one introduces the *constitutive coordinates* n_i^a ; this being the number of moles of the i th constituent C_i in the a th phase. The definitions of Eqs. (10) through (12) remain unaltered, for the n_i^a do not enter into the description of the interaction of the system with its surroundings. Let an amount dn_i^a of C_i be introduced quasistatically into the a th phase of the system. The work done on K shall be $\mu_i^a dn_i$. The quantity μ_i^a so defined is the *chemical potential* of C_i in the a th phase. It is in general a function of all the coordinates of K . Then, identically,

$$dG = \sum_{k=1}^{n-1} x_k dP_k - S dT + \sum \sum \mu_i^a dn_i^a$$

Integrability conditions such as

$$\partial \mu_i^\alpha / \partial T = - \partial S / \partial n_i^\alpha$$

are applications of the first kind. On the other hand, the minimal property of G , derived from the maximal property of S , requires that

$$\sum_i \sum_\alpha \mu_i^\alpha dn_i^\alpha = 0$$

when all virtual states differ only in the values of the constitutive coordinates. If the system is chemically inert, the dn_i^α are subject only to the requirements of the conservation of matter. One then concludes that if there are c constituents and p phases, i.e., $n + pc$ coordinates in all, then the number f of these to which arbitrary values may be assigned is

$$f = c - p + n$$

This typical application of the second kind is the Gibbs PHASE RULE (for inert systems.) This rule is often stated merely for systems with only two external coordinates ($n = 2$, e.g., $x_1 = P$, $x_2 = T$). There must then be no internal partitions within the system, nor may it, for instance, contain magnetic substances in the presence of external magnetic fields.

The beauty and power of phenomenological thermodynamics lies just in the generality and paucity of its basic laws which hold independently of any assumptions concerning the microscopic structure of the systems which they govern. Its quantitative content is limited to conditions of equilibrium. Its conceptual framework is too narrow to permit the description of the temporal behavior of systems, except in as far as it makes it possible to decide which one of any pair of states of an adiabatically enclosed system must have been the earlier state.

Statistical thermodynamics seeks to remedy these deficiencies by making specific assumptions about the microscopic structure of the system K , and relating its macroscopic behaviour to that of its atomic constituents. K is then to be regarded as an *assembly* of a very large number of particles, which, on a non-quantal level, is a mechanical system with, say, N degrees of freedom. A *microstate* of K is a set of values of its N coordinates and its N conjugate momenta. It is out of the question to measure all these at a given time. One therefore constructs a *representative ensemble* \mathcal{E}_K of K , which is an abstract collection of a very large number of identical copies of K . At any time t , the members of \mathcal{E}_K will be in different microstates. Let the fractional number of members of the ensemble whose microstates lie in the range dp, dq about p, q be $\phi dp dq$. Then ϕ is the *probability-in-phase*, and with $d\Gamma = dp dq$

$$\int \phi d\Gamma = 1 \quad (14)$$

The reason for this terminology is implicit in the *Postulate*: *The probability that a given assembly K will, at time t , be in a microstate lying in the range $d\Gamma$ about p, q , is equal to the probability $\phi d\Gamma$ that*

the microstate of a member of \mathcal{E}_K , selected at random at time t , lies in the same range.

The mean value $\langle f \rangle$ of a dynamical quantity f is defined to be

$$\langle f \rangle = \int f \phi d\Gamma$$

If N is sufficiently large, fluctuations about the mean will usually be negligible.

When K is in equilibrium ϕ must be constant in time, and this will be the case if it is a function of the (time-independent) Hamiltonian H of K . Ensemble averages are now assumed to coincide with temporal averages. When, in particular, K is in diathermic equilibrium with its surroundings one can show that ϕ must have the form

$$\phi = \exp[(\Phi - H)/\theta] \quad (15)$$

where Φ and θ are independent of p, q . Then

$$\theta \langle \ln \phi \rangle = \Phi - \langle H \rangle \quad (16)$$

and, because of Eq. (14)

$$\int d \exp[(\Phi - H)/\theta] d\Gamma = 0 = \langle d[(\Phi - H)/\theta] \rangle$$

where d refers to a variation of the macroscopic coordinates of K . Using Eq. (16) and its variation, the relation

$$-\theta d \langle \ln \phi \rangle = d \langle H \rangle - \langle dH \rangle \quad (17)$$

follows. Now $\langle H \rangle$ ($= \bar{U}$, say) is the total energy of the assembly, while $\langle dH \rangle$ is the average of the change of the potential energy, i.e., the work $-dW$ done by the external forces on K . If one writes

$$S = -k \langle \ln \phi \rangle$$

where k is a constant, Eq. (17) becomes

$$k^{-1} \theta dS = d\bar{U} + dW$$

This is identical with the phenomenological relation of Eq. (9) if one formally identifies S with \bar{S} , \bar{U} with \bar{U} and θ with kT . In this way, contact with the phenomenological theory has been established, and the quantities characteristic of the one theory have been *correlated* with that of the other. With this correlation, or interpretation, Φ becomes F . However, because of Eqs. (14) and (15)

$$F = -kT \ln \int \exp(-H/kT) d\Gamma$$

so that if only H is known, the integral on the right (the *partition function*), and thus F , can be calculated. The equation of state of a real gas can thus in principle be obtained from a knowledge of the forces operating within the assembly. This illustrates how the additional information put into the theory yields a correspondingly greater output. Phenomenologically such an equation of state might be written as

$$PV = \sum_{n=1}^{\infty} B_n(T) V^{1-n}$$

but here each of the *virial coefficients* B_1, B_2, \dots must be measured separately.

If the quantum mechanical behavior of matter is taken into account, the fact that one cannot assign precise simultaneous values to canonically conjugate quantities must produce modifications of the details of the statistical theory. However, it is not necessary to consider these here.

THERMOELECTRICITY

Thermoelectricity is the subject dealing with the interaction between temperature gradients and electrical potential differences in solid or liquid materials. In the absence of a magnetic field, there are three thermoelectric effects—the Seebeck, Peltier, and Thomson effects.

The Seebeck effect was discovered by T. J. Seebeck in 1822. Consider a circuit made up of two different materials as shown in Fig. 1. The

FIG. 1. A Thermoelectric circuit composed of two different materials, a and b. The regions enclosed in circles are assumed isothermal at the temperatures shown.

regions around the junctions are assumed isothermal at temperatures T_1 , T_2 , and T_R . If $T_1 \neq T_2$, a voltage V is observed. If the two materials a and b are homogeneous, the voltage V does not depend on T_R or on the temperature distribution along either material, but only on the temperature difference between the junctions. For small temperature differences, the voltage is proportional to the temperature difference

$$V_{ab} = \alpha_{ab}(T_1 - T_2) \quad (1)$$

where α_{ab} is called the Seebeck coefficient of the couple. (It has often been called the thermoelectric power, but this is a poor name since it does not have the dimensions of power.)

The Peltier effect was discovered by J. C. A. Peltier in 1834. In any conductor in which an electric current exists, heat is produced called the Joule heat which is given by

$$P_J = J^2 \rho \quad (2)$$

where P_J is the rate of Joule heat production per unit volume, J is the current density, and ρ is the electrical resistivity. At a junction between dissimilar materials, one finds an additional heat evolved or absorbed when current is present. This additional heat is called the Peltier heat and is given by

$$P_P = \pi_{ab} J_{ab} \quad (3)$$

where P_P is the rate of Peltier heat production per unit cross-sectional area of the junction and π_{ab} is the Peltier coefficient of the junction. Note that the Joule heat is always given off, whereas the Peltier heat may be absorbed or given off depending on the direction of the electric current.

The Thomson effect was predicted by William Thomson (later Lord Kelvin) in 1854 and experimentally established by him several years later. He found that a material in which there was a temperature gradient and an electrical current gave off or absorbed heat in addition to the Joule heat. The difference between the total heat given off and the Joule heat is called the Thomson heat. It is given by

$$P_t = \tau J \nabla T \quad (4)$$

where P_t is the rate of Thomson heat production per unit volume, τ is the Thomson coefficient of the material, and ∇T is the temperature gradient. Note that if either the temperature gradient or the electrical current is reversed in direction, then the Thomson heat reverses also, i.e., if Thomson heat originally was absorbed, then with a reversal of either the temperature gradient or the current density it will be emitted.

The three thermoelectric coefficients are related by the Kelvin relations

$$\pi_{ab} = T \alpha_{ab} \quad (5a)$$

$$\tau_a = -\tau_b = T(d\alpha_{ab}/dT) \quad (5b)$$

where T is the absolute temperature.

It should be noted that the Seebeck and Peltier coefficients as defined here involve two different materials, while the Thomson coefficient involves only one. There are two ways in which Seebeck coefficients for a single material are defined. (1) The relative Seebeck coefficient is defined as the Seebeck coefficient of a couple composed of the given material and a specified standard material such as platinum, lead, or copper. (2) The absolute Seebeck coefficient at temperature T_1 is defined by

$$\alpha_a(T_1) \equiv \int_0^{T_1} (\tau_a/T) dT \quad (6)$$

Since the Seebeck coefficient of a couple is zero at absolute zero temperature, integration of Eq. (5b) yields

$$\alpha_{ab} = \alpha_a - \alpha_b$$

At room temperature, metals have Seebeck coefficients in the range from a few tenths to as high as $40 \mu\text{V}/^\circ\text{C}$ for some alloys. Semi-metals such as bismuth have Seebeck coefficients ranging from about 20 to $40 \mu\text{V}/^\circ\text{C}$, while semiconductors

have Seebeck coefficients from a few microvolts per degree Celsius to as high as 1 mV/°C.

The Seebeck effect is widely used to measure temperature. The thermoelectric circuit, usually called a thermocouple, is made by welding together wires of pure metal or metallic alloys such as copper with constantan, chromel with alumel, or platinum with a platinum-rhodium alloy. For the measurements of very small temperature differences, it is possible to put a number of thermocouples in series so that the voltages add, as shown in Fig. 2. This device is called a thermopile.

FIG. 2. A thermopile made from materials a and b. All of the upper junctions are at temperature T_2 and all of the lower ones are at temperature T_1 .

Devices have also been built utilizing the Seebeck effect to generate electricity directly from a heat source and utilizing the Peltier effect for refrigeration or heat pumping. In these applications the thermoelectric materials are semiconductors, such as Bi_2Te_3 , PbTe or GeTe , with a diameter of 1/8 to 1/2 inch and a length of 1/8 to 3/4 inch. The introduction of a magnetic field into a material may change its Seebeck, Peltier, and Thomson coefficients; it also produces several new effects, called galvanomagnetic and thermomagnetic effects. These include the Nernst, Ettingshausen, and Righi-Leduc effects. In these effects, the electric current or electrical potential difference, the magnetic field, and the temperature gradient or heat flow are all mutually perpendicular. These effects have also been used as a basis for devices which will pump heat or generate electricity directly from a temperature gradient (see HALL EFFECT AND RELATED PHENOMENA).

THIN FILMS

General. The term "thin films" is used for a wide variety of physical structures. Self-supporting solid sheets usually are called foils, when thinned from thicker material by such methods as rolling, beating, or etching, and films, when obtained by stripping a deposited layer from its substrate. Supported thin films are deposited on planar or (in special cases) curved substrates by such methods as vacuum evaporation, cathode sputtering, electroplating, electroless plating, spraying, and various chemical surface reactions in a controlled atmosphere or electrolyte. Thicknesses of such supported films range from less than an atomic monolayer to a few microns ($1\mu = 10^{-4}$ cm). A frequently used thickness measure is the angstrom ($1\text{\AA} = 10^{-8}$ cm). Thin films not forming a continuous sheet are called "island films." Particularly noble metals may condense as islands of considerable thickness (up to $\sim 10^2\text{\AA}$).

In scientific studies and technical applications, the use of well-controllable deposition methods such as vacuum evaporation and cathode sputtering are generally preferred. The film structure is markedly influenced by such deposition parameters as substrate composition and surface structure, source and substrate temperatures, deposition rate, and composition and pressure of the ambient atmosphere (where applicable). In general, the structure of films is more disordered than the corresponding bulk material. Smaller grains, higher dislocation concentrations, and deviations from stoichiometry are typical, and films approach bulk structure only as a limiting case. Under certain growth conditions, films exhibit preferential crystal orientations or even epitaxy. (Epitaxy means that the film structure is determined by the crystal structure and orientation of the underlying substrate.)

Solid thin films are common study objects in most phases of solid-state physics. They supply the samples for the study of general structural and physical properties of solid matter where special beam methods require small quantities of material or extremely thin layers, as for instance in transmission electron microscopy and diffraction, NEUTRON DIFFRACTION, UV spectroscopy, and X-RAY DIFFRACTION AND SPECTROSCOPY. Thin films represent the best means for studying physical effects, where these effects are caused by the extreme thinness of the material itself. Examples are the rotational switching of ferromagnetic films, electron tunnelling phenomena, electromagnetic skin effects of various kinds, and certain optical interference phenomena (see FERROMAGNETISM, SKIN EFFECT AND TUNNELING). Films also are convenient vehicles for the investigation of nucleation and crystal growth, and for

states of extremely disturbed thermodynamic equilibrium.

Presently, films find three major industrial uses: the decorative finishing of plastics, optical coatings of various kinds (mainly antireflection coatings, reflection increasing films, multilayer interference filters, and fluorescent coatings), and in electronic components from transistors over resistor-capacitor networks to such specialized devices as magnetic storage bits, photosensors, and cryotrons. The restricted space only permits the discussion of a few selected research and application areas.

Nucleation, Growth and Mechanical Properties of Films. In vacuum evaporation, molecules or atoms of thermal energy are deposited at a uniform angle of incidence and under well-defined environmental conditions. Most nucleation and growth studies, therefore, have been made on evaporated films. A particle approaching the substrate enters close to its surface a field of attracting short-range London forces with an exchange energy proportional to $-1/r^6$. At a still shorter distance r , repulsive forces proportional to $e^{-r/\text{constant}}$ resist the penetration of the electron clouds of the surface atoms. Due to the atomic or crystalline structure of the substrate, this potential field exhibits periodicity or quasi-periodicity in the substrate plane. The freshly condensed particles migrate over the surface with a jump frequency $i_D \propto \exp(-Q_D/kT)$, or desorb with a frequency $i_{ad} \propto \exp(-Q_{ad}/kT)$, where the activation energy Q_D is often approximately one-fourth of Q_{ad} . Permanent condensation occurs in most cases at distinct nucleation centres which may consist of deep potential wells of the substrate, clusters of condensed particles, or previously deposited "seed" particles of a different material. The number of nuclei formed in the second case is strongly temperature and rate dependent.

Most metals always condense in crystalline form, but the grain size is extremely small at low temperatures (in the order of a few angstroms) and increases markedly with increasing substrate temperatures. Grain size decreases with increasing deposition rates. The condensation of amorphous or quasi-liquid phases at low temperatures has been observed for such metals as antimony and bismuth and a few dielectrics. Some of these materials, on annealing, pass through otherwise unobserved and probably metastable phases.

Stresses of considerable magnitude are often observed in deposited films. The main causes of these stresses are a mismatch of expansion coefficients between substrate and film, enclosed impurity atoms, a high concentration of lattice defects and in very thin films, a variety of surface effects. Often, the stresses resulting from lattice defects can be minimized by the choice of a higher substrate temperature during deposition, or they can be reduced by a post-deposition anneal. Metal films frequently exhibit tensile strengths which are considerably larger than those of the corresponding bulk materials.

Thin-film Optics. Deposited metal mirrors probably represent the oldest optical application of

films. High-quality mirrors usually are produced by the vacuum evaporation of aluminium on an appropriately shaped glass substrate. Often, a glow-discharge cleaning of the substrate or a chromium undercoat is first applied to increase the adhesion of the aluminium. After deposition, the aluminium is protected by anodic oxidation or an evaporated overcoat of SiO, SiO₂, or Al₂O₃.

For SiO, maximum reflectance in the visible spectral region is achieved at a thickness of about 1400 Å. Rapid SiO evaporation reduces the reflectance at shorter wavelengths.

Single or multilayer coatings find increasing use as optical interference filters. These film stacks may consist solely of transparent films of different refractive indices n_i , or a combination of absorbing and nonabsorbing layers. Common low-index materials for glass coatings in the visible region of the spectrum are MgF₂ ($n_i = 1.32$ to 1.37), and cryolite Na₃AlF₆ ($n_i = 1.28$ to 1.34); high-index materials are SiO ($n_i = 1.97$), ZnS ($n_i \approx 2.34$), TiO₂ ($n_i = 2.66$ to 2.69) and CeO₂ ($n_i = 2.2$ to 2.4). The indices are given for the sodium D-line. Various semiconductors are used for infrared coatings.

At each air-film, film-film, or film-substrate interface, the incident light amplitude is split into a reflected and a transmitted fraction according to the Fresnel coefficients

$$f_{j-1} = (\hat{\mathcal{N}}_{j-1} - \hat{\mathcal{N}}_j) / (\hat{\mathcal{N}}_{j-1} + \hat{\mathcal{N}}_j) \text{ and } g_{j-1} = 2 \cdot \hat{\mathcal{N}}_{j-1} / (\hat{\mathcal{N}}_{j-1} + \hat{\mathcal{N}}_j)$$

where j and $j-1$ denote the number of the optical layer counted from the side of the incident beam. $\hat{\mathcal{N}}_j = \mathcal{N} / \cos \theta_j$ for p polarization or $\hat{\mathcal{N}}_j = \mathcal{N}_j \cdot \cos \theta_j$ for s polarization is the effective refractive index, and $\mathcal{N}_j = n_j - ik_j$ the refractive index of the j layer.

$$\cos \psi_j = \sqrt{(n_j^2 + k_j^2 + p_j^2) / 2} - i \sqrt{(n_j^2 + k_j^2 - p_j^2) / 2}$$

$$p_j = 1 + (k_j^2 - n_j^2) [n_0 \sin \theta_0 / (n_j^2 + k_j^2)]^2$$

$$q_j = -2n_j k_j [n_0 \sin \theta_0 / (n_j^2 + k_j^2)]^2$$

The symbol θ_0 is the angle of incidence in the incident medium.

For nonabsorbing film stacks ($k_i = 0$; $i = 1, 2, \dots, m+1$), the over-all reflectance and transmittance may be obtained by summing the multiple coherent reflections between the film boundaries. A more general treatment based on electromagnetic theory yields for amplitude reflectance and transmittance the recursions formulas

$$r_{(j-1)-} = (f_{j-1} + r_{j-} \exp(-2i \Phi_j)) / (1 + f_{j-1} r_{j-} \exp(-2i \Phi_j))$$

and

$$t_{(j-1)-} = (g_{j-1} t_{j-} \exp(-i \Phi_j)) / (1 + f_{j-1} r_{j-} \exp(-2i \Phi_j))$$

$\Phi_j = \Phi_j \cos \Theta_j$ is the effective phase thickness. $\Phi_j = (2\pi/\lambda) \mathcal{N}_j l_j$ where λ is the wavelength in vacuo and l_j is the geometrical film thickness. The recursion is started on the side of emergence, using the initial conditions $r_{m-} = f_m$ and $t_m = g_m$. Intensities are given by $R = |r_0|^2$ and $T = (\mathcal{R} \mathcal{N}_{m+1}/n_0) |t_0|^2$ where \mathcal{R} denotes "real part of." If A_j is the absorption in the layer j , $R + T + \sum_j A_j = 1$.

A single antireflection coating of $\lambda/4$ optical thickness $n_2 l_2$ yields zero reflectance at $n_2 = \sqrt{n_{\text{glass}}}$. A double layer coating of $\lambda/4$ films requires $n_2/n_1 = \sqrt{n_g}$. The transmission of a Fabry-Perot interference filter consisting of a dielectric spacer layer between two partially reflecting metal films is given by $I/I_0 = [(1 + A/T)^2 + (4R/T^2) \sin^2(\delta - \Phi)]^{-1}$ where $\Phi = 2\pi n l \cos \theta/\lambda$. R , T , and A are the reflection, transmission and absorption coefficients of the reflecting layers. The refractive index and thickness of the spacer film are n and l . θ is the angle of refraction in the spacer, and δ the phase change for reflections at the spacer-metal film interfaces. $(I/I_0)_{\text{max}} = (T/(1 - R))^2$ and $(I/I_0)_{\text{min}} = (T/(1 + R))^2$. The band pass half-width is $\Delta\lambda_{1/2} \approx \lambda (1 - R)/m\pi R^{1/2}$ for the interference order m ($m\pi = \Phi$). More, complex coatings and filters, and their various applications, cannot be discussed here. It should be mentioned, however, that films play a very important role today in the accurate determination of the optical constants of many materials, but particularly of metals (see REFLECTION).

Film Electronics. Deposited dielectric film materials in common use are SiO_2 , MgF_2 , ZnS , and various organic compounds. Thin capacitive layers in the 100 to 500 Å thickness region are often produced by the anodization of tantalum and aluminum to Ta_2O_5 or Al_2O_3 , respectively. The breakdown strength and dielectric constant of films approach bulk values, but might be reduced by surface roughness, structural faults, and lower density. According to the Lorentz-Lorenz formula, the dielectric constant D changes with reduced density ρ as $dD/d\rho = 3C/(1 - C\rho)^2$, where C is a constant depending on the material. On metal-dielectric-metal films, quantum mechanical tunneling through the dielectric film becomes observable below a dielectric thickness of about 100 Å. For applied voltages less than the metal-insulator work function ϕ , the tunneling current density J is proportional to the applied voltage V , demonstrating that the low-voltage tunneling resistance is ohmic. $J = (qV/h^2 s)(2m^* \phi)^{1/2} \exp[-(4\pi s/h)(2m^* \phi)^{1/2}]$. At high applied voltages ($qV > \phi$), the current increases very rapidly: $J = (q^2 V^2/8\pi h \phi_s^2) \exp[-(8\pi s/3h q V)(2m^*)^{1/2} \phi^{3/2}]$. s is the insulator thickness, m^* the electronic effective mass, and q the electron charge. Thicker dielectric films may exhibit in high fields appreciable Schottky or avalanche currents when they are greatly disordered.

Polycrystalline metal films generally show, due to their low structural order, a larger resistivity than the bulk material. According to Matthiessen's rule, the total resistivity can be expressed as

$\rho = \rho(t) + \rho(i)$ where $\rho(t)$ is the temperature-dependent resistivity associated with scattering by lattice vibrations, and $\rho(i)$ is a temperature-independent resistivity caused by impurity or imperfection scattering. Very thin specimens with a thickness comparable to the electron mean free path show a $\rho(i)$ rapidly increasing with decreasing thickness. This increase is caused by an increasing contribution of non-specular electron scattering at the film surfaces. By annealing a metal film, $\rho(i)$ might be reduced permanently. A large $\rho(i)$ results in a small temperature coefficient α .

Many known superconductors can be deposited as super-conductive films (see SUPERCONDUCTIVITY). Through thin-film experiments, the energy gap in semiconductors can be measured, and material parameters, such as the penetration depth of magnetic fields, can be studied at dimensions less than the coherence range.

Studies of semiconductor films have shown many facets. The properties of epitaxial films have mainly been investigated on Ge and Si, and to a lesser degree on III-V compounds. Much work has been done on polycrystalline II-VI films, particularly with regard to the stoichiometry of the deposits, doping and post-deposition treatments, conductivity and carrier mobility, photo-conductance, fluorescence, electroluminescence, and metal-semiconductor junction properties. Among other semiconductors, selenium, tellurium, and a few transition metal oxides have found some interest.

Film resistors, capacitors, and interconnected R-C networks on planar glass or ceramic substrates are finding widespread industrial use. Common resistor materials are carbon, nichrome and tin oxide in individual components; and nichrome, tantalum, tantalum nitride, SiO-chromium cermet, and cermet glazes in planar networks. Gold, copper, aluminum, or tantalum are used for termination lands, connection leads, and capacitor plates. SiO , MgF_2 and Ta_2O_5 serve as film capacitor dielectrics and crossover insulation. The geometrical configuration of the desired component or circuit pattern is obtained either by deposition through mechanical masks or by removing from a continuous sheet the undesired portions after the deposition process is completed. This removal is frequently accomplished by a combination of photolithographic and etch processes.

The minimum length l and width w of a resistor are calculated from the given resistance R , the sheet resistance \mathcal{R} in ohms per square, dissipated power P , and permissible power dissipation per square inch \mathcal{P} by use of the formulas $w = \sqrt{(P \cdot \mathcal{R})/\mathcal{P} \cdot R}$ and $l = wR/\mathcal{R}$. The capacitance of film capacitors is given by $C = 0.225 D(N-1)A/t$, where C is the capacitance in picofarads, D the dielectric constant, N the number of plates, A the area in square inches, and t the dielectric thickness in inches.

Thin-film semiconductor devices have not yet reached the production stage, mainly due to difficulties in controlling the film surface and

interface properties. Various barrier layer diodes have exhibited impressive rectification ratios, but limited breakdown strength and low speed due to their large specific capacitance. Of the many film TRANSISTOR concepts proposed, the insulated gate field effect device looks the most promising and manufacturable. Its structure consists of a minute metal-dielectric-semiconductor capacitor. The semiconductor strip carries current between two terminals called source and drain. A field applied between metal "gate" and source modulates the semiconductor conductance and consequently the source-drain current. Usable semiconductor materials with a sufficiently low concentration of interface states are CdS, CdSe, and tellurium. These devices exhibit pentode-like characteristics with voltage gains ranging from 2.5 at 60 Mc to 8.5 at 2.5 Mc. The gain band width product G.B., which is equal to the transconductance divided by 2π times the gate capacitance, reaches values of about 20 Mc. It is determined by $G.B. = \mu_d V_D / 2\pi L^2$, where μ_d is the effective drift mobility of the electrons, V_D the source-drain potential, and L the source-drain spacing which is usually chosen between 5 and 50μ . Special film semiconductor devices in industrial use are various types of photodetectors.

Magnetic Films. Magnetic thin films of nickel-iron (usually desposited at an 80:20 composition by weight) exhibit a number of unusual properties, which have led to many experimental and theoretical studies, as well as to important applications in binary storage and switching, magnetic amplifiers, and magneto-optical Kerr-effect displays.

Such "Permalloy" films have two stable states of magnetization, corresponding to positive and negative remanence. When deposited in a magnetic field or at an oblique angle, they exhibit uniaxial anisotropy. In practice, this anisotropy shows some dispersion, since it results from the alignment of local lattice disturbances. The stable states result from the minimization of the free energy $E = MH_L \cos \theta - MH_T \sin \theta - K \sin^2 \theta$, where the last term represents the anisotropy energy, and θ is the angle between the magnetization M and the easy axis. From an inspection of the derivatives of this equation follows the hard-direction straight-line and the easy-direction square hysteresis loops of anisotropic films. In the latter case, the magnetization is always either $+M$ or $-M$, and the change occurs at $H_L = \pm H_K$. The transitions from unstable to stable states occur at $\partial^2 E / \partial \theta^2 = 0$, resulting in a critical curve $H_L^{2/3} + H_T^{2/3} = H_K^{2/3}$ which has the form of an asteroid enclosing the origin (see MAGNETISM).

An important feature of magnetic films is the high speed with which the state of magnetization can be reversed. Dependent on film properties and magnetic fields, three modes of magnetization reversal occur: Domain wall motion, incoherent rotations, and the extremely fast coherent rotation of the magnetization. Wall-motion switching is expected when the driving fields are smaller than the critical values. Modern high-

speed film computer memories attempt to utilize the rotational switching mode.

TIME

Too many interpretations of the concept of time are based on one of the following two kinds of oversimplification. Philosophers have speculated about time on the premise that it is a primary notion and can be abstractly defined without bothering about the implementation of the definition. Conversely, the physicists, before Einstein, had a tendency to take time for granted and to use it as a parameter without further questioning its definition. Psychologists may have been the first to make a step in the right direction by trying to relate the concept of time to actual perceptions.

Nowadays, the physicist has become aware of the necessity of providing operational definitions of the concepts he uses, and it is generally acknowledged that the very concept of time depends upon the possibility of the repetition of events that may be considered identical or, at least, that have a common recognizable feature. However, the far-reaching implications of this idea are seldom realized, and it is not infrequent to read otherwise respectable discussions based on a notion so "obvious" that its vagueness remains completely unsuspected, namely, the notion of a "clock."

Assigning to time the character of a self-contained concept and assuming the existence of appropriate "clocks" showing the flow of this "time" is putting the cart before the horse. In a more refined approach, an a priori time

concept is accepted and principles are formulated by virtue of which a motion taking place in some specified conditions is uniform. But even such a procedure amounts to a self-deception, as the actual definition of time is then camouflaged behind those "principles." (For example, the essential of the definition of time in classical mechanics lies in Newton's first law). In brief, the true primary operation is the *arbitrary choice* of a repeatable phenomenon that may be used in the definition of a clock. The rate of flow of "time" is then implied by this choice, that is, the choice of the fundamental clock *is* the definition of time.

For practical purposes, it is appropriate to limit the freedom inherent in the choice of a clock by specifying convenient properties to be imposed on the resulting time scale. The main such properties are the availability of a sufficiently perennial master "clock" and the possibility of devising wieldy secondary clocks, for everyday use, that give reproducible and consistent readings endowed with a property of additivity. The first master clock that suggested itself to mankind was provided by the rotation of the earth on its axis and around the sun. The unit of time thus defined and its aliquot parts gave birth to the first astronomical time scales (mean solar day, tropical year), which served as a background for the development of classical mechanics and astronomy. A large number of phenomena were discovered (e.g., the beats of a good watch) that bear a linear relationship to that time scale. Any of the "linear systems" involved could be used as a secondary clock. Then, when the measuring techniques improved, it appeared that the mutual linearity of those phenomena was only an approximation. This discovery brought about a mild crisis of the metrology of time. The crisis was readily dismissed by stating that the rotation of the earth was not really uniform (as compared to "more accurate" clocks). In fact, the situation had a deeper purport: two descriptions of the fundamental master clock, that had been hitherto considered equivalent, appeared to be inconsistent, and the question of the *choice* of the clock was brought to the foreground again. The difficulty was temporarily settled in 1955 by relating the astronomical time scale to one particular period (tropical year 1900.0 \approx 31 556 925.975 seconds), and work is under way in order to submit a new definition of the second to the Twelfth International Conference of Weights and Measures in 1966. This definition will be based on the frequency of the radiation emitted in the transition between two specified atomic energy levels. Implemented by a so-called atomic clock, it will yield standards reproducible up to a relative error of 2×10^{-11} .

Newtonian time, a basic feature of the whole body of classical mechanics, is practically the astronomical time, operationally defined as above, complemented by the following extra postulate. Let any single observer, standing still on earth, determine the (improved as above)

astronomical time scale; the time scale so obtained is then to be used by every "observer," whatever his motion with respect to the first one. This postulate expresses, for each "observer," one choice of the master clock among infinitely many possible choices, and as such it is legitimate. When it was stated, it was also consistent with the contemporaneous physical knowledge. Later on, the physicists grew accustomed to certain properties derived from the choice of Newtonian time and space and from other postulates of mechanics and electromagnetism, until a calamity happened which was similar to what has befallen astronomical time: the improvement of the measuring techniques showed that one empirical fact (namely, that the velocity of light in the laboratory frame of reference is independent of the motion of the emitter) was not compatible with all of those properties. Again a choice was necessary. The analysis of special relativity disclosed which of the properties at stake were incompatible. The decision as to which to drop was largely a matter of convenience. Einstein's choice (justified by strong operational reasons) was to drop the universality of time and space in order to retain more physical postulates. From then on, time and space ceased to be absolute concepts (see RELATIVITY). It is worth mentioning that the presence of such a fundamental choice at the basis of the special-relativistic theory of time is not always recognized.¹

As the choice of the master clock may not be made any more by one "observer" on behalf of another one, the choice has to be decided upon for each "observer" separately. Special relativity's specification is that each inertial "observer" shall use the time scale defined by means of a conventional atomic "clock" at rest with respect to himself. This procedure leads to the concept of proper time, which enjoys a mathematically invariant character and plays, for inertial systems, the part formerly played by the universal time (see RELATIVITY).

When it comes to comparing the descriptions of the universe as made by "observers" whose motions relative to an inertial frame involve an acceleration, use is generally made of "general covariance," which permits a straightforward generalization of proper time. The relevant mathematical framework is that of general RELATIVITY. However, the interpretation of the general-relativistic proper time in terms of everyday experience involves instantaneous inertial frames, which are not embodied by any material system in this kind of problem. Therefore, the explicit relationship between proper time and the time actually measured by a material device called a clock is by no means clear.² In fact, the use of proper time in accelerated systems again implies a choice of the master clock, and in the present instance the choice has the drawback of being fairly abstract. Notwithstanding the largely widespread opinion, general covariance may not be the most convenient tool for the study of time in noninertial frames of reference. The problem of time measurements in

such frames is an open problem, on which practically everything remains to be done.

Although quantum mechanics has not brought a revolution in the conception of time (which remains an evolution parameter in the physical equations), it has suggested one approach which, if it ever turns out to be fruitful, would seriously upset the current notion of time. This approach consists in an attempt to quantize space-time itself, i.e., to assign to space and time jointly a discontinuous structure, involving elementary lengths and durations, instead of simply quantizing phenomena in a continuous space-time framework. As no consistent formalism of practical use has been developed so far along these lines, it suffices to mention a couple of recent references.^{3,4}

TRANSFORMER*

In elementary form, a transformer consists of two coils wound of wire and inductively coupled to each other. When alternating current at a given frequency flows in either coil, an alternating electromotive force (emf) of the same frequency is induced in the other coil. The value of this emf depends on the degree of coupling and the magnetic flux linking the two coils. The coil connected to a source of alternating emf is usually called the primary coil, and the emf across this coil is the primary emf. The emf induced in the secondary coil may be greater than or less than the primary emf, depending on the ratio of primary to secondary turns. A transformer is termed a step-up or a step-down transformer accordingly.

Most transformers have stationary iron alloy cores, around which the primary and secondary coils are placed. Because of the high permeability of iron alloys, most of the flux is confined to the core, and tight coupling between the coils is thereby obtained. So tight is the coupling between the coils in some transformers that the primary and secondary emf's bear almost exactly the same

ratio to each other as the turns in the respective coils or windings. Thus, the turns ratio of a transformer is a common index of its function in raising or lowering potential.

A simple transformer coil and core arrangement is shown in Fig. 1. The primary and secondary coils are wound one over the other on an insulating coil tube or form. The core is laminated to reduce eddy currents. Flux flows in the core along the path indicated, so that all the core flux links both windings. In a circuit diagram, the transformer is represented by the symbol of Fig. 2.

FIG. 1. Transformer coil and core.

FIG. 2. Simple transformer.

In order for a transformer to deliver secondary emf, the primary emf must vary with respect to time. A dc potential produces no voltage in the secondary winding or power in the load. If both varying and dc potentials are impressed across the primary, only the varying part is delivered to the load. This comes about because the electromotive force e in the secondary is induced in that winding by the core flux ϕ according to the equation

$$e = - \frac{N d\phi}{dt}$$

This equation may be stated in words as follows: The voltage induced in a coil is proportional to the number of turns and to the time rate of change of magnetic flux linking the coil. This rate of change of flux may be large or small. For a given potential, if the rate of change of flux is small, many turns must be used. Conversely, if a small number of turns is used, a large rate of change of flux is necessary to produce a given potential.

Without transformers, modern industry could not have reached its present state of development. The highest potentials which are economically feasible in ac generators are of the order of 20 kV. Transmission of power over long distances is most economical at high potentials which have

* Figures 1 and 2 and information contained in this article are based on the book "Electronic Transformers and Circuits" by Reuben Lee, New York, John Wiley & Sons, Inc., and are used with permission of the publisher.

reached levels of 500 kV and over. The higher the potential of the transmission line, the greater is the amount of power that can be transmitted over a given line conductor. The upper limit of potential is determined by insulation. Insulation research and development have resulted in completely surge-proof transformers, and have made possible power systems which are capable of withstanding lightning surges. At the utilization end of power systems, potential is successively lowered by means of step-down transformers to make power available in safe, useful form. Instrumentation and control of electrical power also require special forms of transformers.

An ideal transformer is defined as one which neither stores nor dissipates energy. Departures from the ideal transformer are caused by:

- (1) Winding resistance and capacitance,
- (2) Leakage inductance (due to flux which does not link both windings),
- (3) Core hysteresis and eddy current losses,
- (4) Magnetizing current.

Factors (1) and (2) above contribute to regulation, or the difference between secondary emf at no-load and full-load. This property is most important with variable load. Although no actual transformer is ideal, some transformers very nearly approach it. For example, in a 50-kVA rectifier transformer winding resistance amounts to 1 per cent, and leakage reactance 3 per cent, of the applied emf; core loss is 0.6 per cent of rated power, and magnetizing current is 2 per cent of rated current. Efficiency (output power divided by input power) is 98.4 per cent for this transformer.

Transformers are needed in electronic apparatus to provide the different values of potential for proper vacuum, gas or solid-state device operation, to insulate circuits from each other, to furnish high impedance to alternating current but low impedance to direct current, to change from one impedance level to another, to connect balanced lines to unbalanced loads, and to maintain or modify wave shape and frequency response at different potentials. Electronic transformers differ from power frequency transformers in the range of impedance levels, frequencies, size and weight. Categories of electronic transformers are: (1) Power, (2) frequency range, and (3) pulse.

Electronic power transformers are generally used to supply rectifiers at potentials ranging from 150 volts to 500 kV. Recent years have seen the widespread use of inverter transformers which convert dc potentials to higher dc potentials in conjunction with semiconductor rectifiers. A typical circuit is that of Fig. 3. Here the transformer output is a rectangular alternating wave which is often rectified again to produce dc output at increased potential.

Frequency range transformers are used in applications where the frequency varies, including audio, video, carrier and control frequencies. Such frequencies vary from a fraction of 1 cps to uhf (300 to 3000 Mc). Transformers may be wide-band or narrow-band in frequency

response, and the core material changes accordingly. In wide-band transformers, the ratio of lowest frequency to highest frequency may be as great as 10^5 . Narrow-band applications use mostly high frequencies and operate over a small percentage of the carrier frequency (e.g., 50 to 55 Mc).

FIG. 3. Solid-state controlled rectifier and transformer from dc to ac inverter.

Pulse transformers are used in radar modulators and computers. In radar applications, the pulses are usually rectangular and occur repetitively. Pulse widths range from 0.1 to 200 μ sec. Peak ratings are large, from 100 to 50 000 kW. Secondary emf may range up to 300 kV for operation of high-power magnetrons and klystrons. Computer transformers are usually small, have ferrite cores and operate from current pulses to drive core matrices.

Advances in transformer technology depend largely on development of new core and insulation materials, conductor arrangements, measuring techniques and methods of application. By these means, transformers come into use at higher frequencies, with better balance, smaller size or higher power than formerly thought possible.

TRANSISTOR

Few inventions have had as much impact on the electronics industry as the invention of the transistor. Even though the first transistors differed greatly in structure and method of fabrication from those which are in use today, many of the advantages were immediately recognized. Because it was the first workable solid-state amplifier with no physical mechanism which would wear out during its life and because it was relatively simple to fabricate, it immediately became apparent that the transistor would replace a large fraction of the vacuum tubes which were used in radios and electronic systems.

The point-contact transistor¹ was invented by J. Bardeen and W. H. Brattain at Bell Telephone Laboratories in 1948. Its structure (Fig. 1)

FIG. 1. Point-contact transistor.

consists of a piece of *n*-type germanium about $0.05 \times 0.05 \times 0.005$ inches on which are placed two sharpened points (a beryllium-copper emitter and a phosphor-bronze collector) approximately 0.002 inches apart. Each of these points exhibits rectifying diode type current-voltage characteristics. The operation of the transistor depends on the injection of holes into the *n*-type material through the forward-biased emitter point and the collection at the reverse-biased collector point. The third electrode in the transistor is a low resistance, nonrectifying contact made to the *n*-type germanium and is designated the base electrode. Power gain is achieved in this structure because the collector current increases at a rate equal to two or three times the emitter current and because the reverse-biased collector terminals can be matched in a circuit to a higher impedance load than the input emitter impedance.

The junction transistor^{2,3} exhibits definite advantages over the point-contact transistor and has obsoleted this latter type. In a junction transistor, the rectifying characteristics are obtained within the bulk of the semiconductor crystal by placing different types of impurities at different points in the crystal. The structure of an *n-p-n* junction transistor is illustrated in Fig. 2. The emitter and collector regions have an excess of *n*-type impurities while the base region has an excess of *p*-type impurities. The transition from *p*-type material to *n*-type material is designated as a *p-n* junction. In order to achieve

transistor action it is necessary to have the emitter and collector *p-n* junctions in close physical proximity (0.001 inches or less).

Junction transistors are generally made from germanium or silicon crystals. Germanium technology preceded silicon by approximately five years, but silicon offers several advantages—operation at higher temperatures, lower power consumption, and greater surface stability—so that silicon transistors are rapidly overtaking germanium transistors. Germanium offers only

FIG. 2. Structure of *n-p-n* grown-junction transistor.

definite advantages in the high-frequency area because electrons and holes travel faster in germanium than in silicon. Transistors have also been made from other semiconductor materials such as gallium arsenide,⁴ but this technology is relatively new and has not been demonstrated to be as useful. In addition, there are also *p-n-p* transistors where the type of material used for emitter, base, and collector regions is reversed from those shown for the *n-p-n* transistor in Fig. 2. The basic difference is that the polarity of all the operating voltages and currents are opposite for these two types of transistors.

The operation of the *n-p-n* transistor hinges upon the injection of electrons across the forward biased emitter *p-n* junction into the base region of the transistor. Once these electrons are injected across the junction they diffuse across the base and arrive at the reverse-biased collector junction. While the emitter junction acts as a source for these electrons, the reverse-biased collector junction acts as a sink for them. We measure the efficiency of such transistor by the current multiplication factor α_F defined as

$$\alpha_F = \frac{\partial I_C}{\partial I_E} \quad (1)$$

where I_C is the collector current and I_E is the emitter current. In most junction transistors α_F is between 0.95 and 1.00.

The junction transistor can be connected in a circuit so that any one of its three terminals is the common terminal. Figure 3 shows an *n-p-n* transistor connected in the common emitter configuration with typical operating voltages and currents. Note that in this connection a small incremental increase in base current produces a

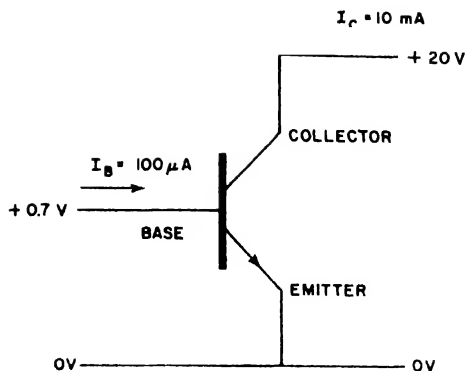

FIG. 3. Circuit symbol and typical potentials for n - p - n silicon junction transistor.

sizeable increase in collector current. This ratio is defined as

$$h_{FE} = \frac{\partial I_C}{\partial I_B} = \frac{\alpha_F}{1 - \alpha_F} \quad (2)$$

Typical values of h_{FE} are between 20 and 200.

There are many types of junction transistors, dependent on the specific method of fabrication chosen. In all cases n -type impurities such as phosphorus, arsenic, or antimony, and p -type impurities such as boron, indium, gallium, or aluminum are introduced into the appropriate regions of the transistor. In a grown-junction transistor,⁵ the impurities are introduced at the time that the silicon or germanium crystal is being fabricated. In an alloy-junction structure,⁶ the impurities are introduced by melting a pellet of the appropriate doping material on the surface of the semiconductor and regrowing the crystal. Diffused junction transistors^{7,8} are produced by placing the semiconductor material in a furnace at an elevated temperature in an atmosphere containing the desired doping element. The doping material then diffuses⁹ into the semiconductor crystal and substitutionally replaces some of the silicon or germanium atoms in the crystal lattice. A region of the opposite type can be created by overcompensating, diffusing into the same region the other type of impurity to a concentration in excess of that previously diffused.

Figure 4 shows the structure for a silicon planar transistor.¹⁰ This transistor is produced by diffusing boron impurities into n -type silicon in order to create the p -type base region and later diffusing phosphorus to create the n -type emitter region. Note that the surface of the transistor is covered by a layer of silicon dioxide (quartz) which acts as a protection for the exposed p - n junctions; such layer assures a very high-reliability transistor.

This transistor is also economical to fabricate because mass processing techniques can be utilized; several hundred identical transistors can be produced on a slice of silicon approximately one inch in diameter. The precise geometrical control achieved by using diffusion

FIG. 4. Cross-sectional view of silicon n - p - n planar transistor.

techniques results in very reproducible electrical characteristics. In order to fabricate a planar transistor we take advantage of the fact that boron and phosphorous do not diffuse through the protecting silicon layer. Hence, it is possible to cover an entire slice of silicon with the oxide and cut holes in the oxide of a geometrical pattern corresponding to that of the desired diffusions. The same techniques can also be used for making integrated circuits.¹¹ In an integrated circuit, the transistors, diodes, resistors, and capacitors are produced on the same slice of silicon by properly controlled diffusion methods.

Transistors are now being used extensively in all electronic equipment. As amplifiers they are useful up to frequencies of several hundred megacycles and at power levels up to 100 watts. However, one of the largest applications of transistors has been as a switch in computers. The electrical characteristics of a transistor are nearly ideal for this type of application in that they closely simulate a relay in its open and closed positions. The fastest and most reliable computers in use today are all transistorized.

TRANSPORT THEORY (Radiative Transfer)*

When light passes through an atmosphere, it may be scattered and absorbed. When neutrons move through a medium, collisions with the nuclei of the material may result in absorption of the neutrons, changes in their direction and energy, and sometimes, by the fission mechanism, production of more neutrons.

These two phenomena are examples of transport processes. The problem of specifying the radiation field in an atmosphere stems back to Rayleigh's investigations on the illumination of a sunlit sky. The astrophysicists refer to this general subject as *radiative transfer* and have studied it for well over half a century. Interest in neutron transport has perforce been of more recent origin.

If light is thought of as consisting of photons, then there is seen to be a very strong similarity between neutron transport and radiative transfer. The former process is both complicated and made more interesting by the possibility of fission in various materials. Other physical phenomena, such as the passage of γ -rays through a medium, possess many characteristics of the two processes that have been mentioned.

Fortunately, it is possible to develop a mathematical structure which encompasses all these

phenomena. The situation is similar to that in classical diffusion theory, where the same mathematical equations may be interpreted, for example, to yield information concerning the distribution of heat in a metal or the flow of one material into another. The equations describing particle transport are, however, of a much more complicated nature than many of those of classical physics and are only now beginning to yield to the techniques of the mathematicians.

All the transport processes described above have the property that the moving particles involved may be thought of as interacting or colliding with fixed centers or nuclei of the material through which they are passing. The moving particles do not collide with each other. The interactions, in the situations which we will consider, are strictly independent and local events—a particle is affected only by a scattering center in its immediate neighborhood. Most important is the fact that a probability for such an interaction may be assigned:

Probability of interaction in moving a distance Δ

$$= \Sigma \Delta + (\text{terms of higher order in } \Delta) \quad (1)$$

The quantity Σ , called the *macroscopic cross section*, is dependent upon the kind and density of the medium, the type of moving particle (photon, neutron, etc.), the particle energy, etc. Determination of Σ is a complicated problem of experimental and theoretical physics.

An interaction or collision may result in a change in the direction of the moving particle (scattering), disappearance of the particle (absorption), or production of new particles of the same kind (fission). Scattering may produce no energy loss (elastic), or it may involve energy loss (inelastic). Such interactions may affect the transport medium, though for most purposes this change may be neglected. Again, the actual physical determination of the result of a collision is frequently a difficult task. Such information, together with the quantity Σ , must be considered for our purposes as already known⁶.

The central problem of transport theory as we view the subject, may now be formulated. Given a physical medium with all parameters, such as the macroscopic cross section and the results of interaction, specified, let a population of particles of given kind, direction, energy, etc., be present in the material at initial time, $t = 0$. Let any internal or external sources of such particles be given. Describe as a function of position, direction, energy, etc., the expected particles population at any time $t > 0$.

Clearly, the transport process is probabilistic in nature. It is customary, because of the difficulty of the subject, to study expected value theory, although some investigations of a more detailed type have been made. Often the term "expected" is dropped in discussion so that "expected flux" becomes simply "flux," etc. It is important to remember that this is done only as a matter of convenience in writing.

From Eq. (1) further information concerning the probability of collision may be obtained. Write

$p(x)$ = Probability that a particle moves a distance x without collision (2)

Then,

$p(x + \Delta) = (1 - \Sigma\Delta) p(x) + (\text{terms of higher order in } \Delta)$ (3)

Equation (3) gives

$$\frac{dp}{dx} = -\Sigma p(x)$$

and, if Σ is constant,

$$p(x) = e^{-\Sigma x} \quad (4)$$

This is the well-known exponential law.

To find the average distance a particle moves without collision observe that

$F(x)$ = Probability that the first collision occurs at some $X < x$ (5)

$$1 - e^{-\Sigma x}$$

Then the average or expected value of X is

$$E(X) = \int_0^x x dF(x) = \int_0^x \Sigma x e^{-\Sigma x} dx \quad (6)$$

$$\frac{1}{\Sigma}$$

This average distance between collisions is referred to as the *mean free path*, usually denoted λ .

Suppose the half space $x > 0$ is filled with a medium characterized by constant macroscopic cross section Σ . If a flux of N_0 particles impinges perpendicularly on $x = 0$, then the expected flux at $x = d$ of particles which have made no collision is, from Eq. (4),

$$N(d) = N_0 e^{-\Sigma d} \quad (7)$$

When the collision process involves only absorption, $N(d)$ is the total expected flux at $x = d$, but if scattering and fission processes occur $N(d)$ may be quite different from the total flux. These physical events complicate transport theory greatly.

Some idea of the complexities introduced by the fission process may be obtained by study of a very simple mathematical model in which particles are allowed to move only to the right or left in a rod (i.e., a line segment) of length a . Suppose that in an interaction the colliding particle disappears and two new ones emerge, one moving left and one moving right (binary fission). All particles have the same speed c , and Σ is constant. Finally, assume that the process is such that the average particle density is the same at one time as it is any other, so that time dependence may be

neglected. Denote by $cu(x)$ and $cv(x)$ the right and left fluxes at x . Then?

$$u(x + \Delta) = (1 - \Sigma\Delta)u(x) + \Sigma\Delta u(x) + \Sigma\Delta v(x) + (\text{higher order terms in } \Delta) \quad (8)$$

which leads to

$$\frac{du}{dx} = \Sigma v \quad (9)$$

Similarly

$$-\frac{dv}{dx} = \Sigma u \quad (10)$$

If one left-moving particle per second is introduced at $x = a$, with no source at $x = 0$, then

$$u(0) = 0, \quad cv(a) = 1, \quad (11)$$

and the system of Eqs. (9) through (11) yields

$$cu(x) = \frac{\sin \Sigma x}{\cos \Sigma a}, \quad cv(x) = \frac{\cos \Sigma x}{\cos \Sigma a}, \quad 0 \leq x \leq a \quad (12)$$

These results are obviously quite different from any that would be given by a simple attenuation law such as Eq. (7). Indeed, because of the fission assumed, a collision results in an increase, rather than a decrease, in the particle population. The case $a = \pi/2\Sigma$ is of especial interest. For a rod of that length neither $u(x)$ nor $v(x)$ is defined. Physically, the system is just *critical*. A time-independent population cannot prevail with the source specified. Equations (9) and (10) no longer hold when $a \geq \pi/2\Sigma$.

This observation does not imply that supercritical systems cannot be analyzed. To do so requires explicit introduction of the time variable². Equations (9) and (10) are replaced by

$$\frac{1}{c} \frac{\partial u}{\partial t} + \frac{\partial u}{\partial x} = \Sigma v(x, t) \quad (13)$$

$$\frac{1}{c} \frac{\partial v}{\partial t} - \frac{\partial v}{\partial x} = \Sigma u(x, t) \quad (14)$$

with suitable boundary and initial conditions. For large times it may be shown that the solutions to these equations can be written *approximately* as

$$u(x, t) = u_0(x) e^{\alpha t}, \quad v(x, t) = v_0(x) e^{\alpha t} \quad (15)$$

for some α . When $a > \pi/2\Sigma$, α is positive so that the particle fluxes build up exponentially in time. This exponential increase is observed in actual experiments involving fissionable materials. When the particle population in a system is just sustained without introduction of additional particles (sources) the system is just critical (see CRITICAL MASS).

It is possible to consider other relatively simple mathematical models of transport phenomena and from them to determine much valuable information. Any attempt to solve a "realistic" physical problem, however, usually results in

great difficulties. The general transport equation is of the form

$$\frac{D N}{D t}(\bar{r}, \bar{v}, t) = -\Sigma(\bar{r}, \bar{v}, t) N(\bar{r}, \bar{v}, t) + \int_{\bar{v}'} K(\bar{r}, \bar{v}' \rightarrow \bar{v}, t) \Sigma(\bar{r}, \bar{v}', t) N(\bar{r}, \bar{v}', t) d\bar{v}' + S(\bar{r}, \bar{v}, t) \quad (16)$$

subject to boundary and initial conditions dependent upon the geometry. In Eq. (16), $\frac{D}{D t}$ is the total time derivative, \bar{v} is the velocity, and K is a function that gives the density of particles emerging at velocity \bar{v} from a collision at \bar{r} at time t involving a particle moving at velocity \bar{v}' . Sources are represented by S . It is clear that Eq. (16), while linear, has a much more complicated structure than many of the classical equations of mathematical physics. Little is known of the mathematical properties of its solutions.

The complexity of the general transport operator, coupled in some cases with the urgencies of designing atomic weapons, nuclear reactors, etc., has resulted in a plethora of approximate methods for its treatment.^{3,4,6} It should be pointed out that no such scheme can possibly give satisfactory results without good knowledge, either experimental or theoretical, of the physical parameters involved. Great efforts have been made toward accurate determinations of Σ and K .

A very simple approximation to transport theory may be obtained by considering all particles of the same energy, with K a constant. Truncated expansion in Legendre polynomials of the angular dependence of pertinent functions then yields neutron diffusion theory. The resultant equation is identical in structure to the heat equation, allowing classical solutions to be used in many problems. This approximate theory is valid only under quite stringent conditions, but it often gives surprisingly good results. Variants of simple neutron diffusion theory are numerous, including age theory and n -velocity group theory to account for energy changes, and the P_n -approximation, in which more terms of the Legendre series are retained. Non-constant K may also be included. A method of calculating the integral in Eq. (16) by Gaussian quadrature is closely connected with the P_n -approximation.²

The advent of the high-speed computing machine has made finite difference schemes for solving the transport equation quite feasible. One of the most successful is the so-called S_n -method, characterized by the fact that angular dependence of the flux is assumed to be piecewise linear.¹

Another popular attack on transport problems is via the Monte Carlo method.⁶ There, the particle motion is actually simulated by machine computation. Particles suffer collisions, change direction, lose energy, etc., according to specified probabilities. The machine traces the history of a single particle from its appearance in the system until the particle leaves or is no longer of interest. Events in the particle's history are allowed to

happen randomly, the computing machine deciding on the event according to a preassigned (and presumably physically correct) probability distribution. This method is hence stochastic in nature, although expected values are usually taken after a sufficiently large particle population has been examined. The Monte Carlo technique is often used when the geometry of the problem is complicated.

A completely different approach, of both analytical and computational interest, to the over-all problem of particle transport has been used rather extensively over the last twenty years by the astrophysicists, although it is as yet not well known to workers in neutron theory. This device, called the "method of invariance" or "invariant imbedding," focuses attention on the particles *emergent* from the medium.^{2,7} Equations are derived by considering the relationship between the flux out of a system and the corresponding flux emergent from a slightly larger system. Invariant imbedding has several computational advantages, especially when the emergent flux is the quantity of primary physical interest. The imbedding equations are nonlinear, but in some ways are easier to handle than equations like Eq. (16). At present, the method can be successfully applied only to systems with considerable symmetry.

Transport theory is still a relatively young subject. Much remains to be accomplished, both from the viewpoint of the physicist and from that of the mathematician.

TRANSURANIUM ELEMENTS

Those elements heavier than uranium, element 92. The transuranium elements are all radioactive and have half-lives too short to have existed in nature since their original creation. They were

all discovered and produced by nuclear synthesis. The presently known (1964) transuranium elements have the following names and symbols: 93, neptunium (Np); 94, plutonium (Pu); 95, americium (Am); 96, curium (Cm); 97, berkelium (Bk); 98, californium (Cf); 99, einsteinium (Es); 100, fermium (Fm); 101, mendelevium (Md); 102, (name in question) and 103, lawrencium (Lw).

It is reasonable to assume that elements heavier than lawrencium, 103, will be produced either through the bombardment of the heavier transuranium elements with heavy ions (heavier than helium ions) in an accelerator or in specially tailored thermonuclear devices detonated underground. The half-lives of these elements are expected to be so short as to make conventional chemical identification difficult up to elements 104 and 105 and very difficult beyond these. Perhaps chemical identification can be made in some cases by using simple and fast methods, as for example, those involving migration of gaseous atoms or ions, volatility properties, reactions with surfaces, or gas flow reactions. The historic requirements for the discovery of a new element, namely complete chemical identification and separation from all previously known elements, have already had to be changed with the discovery of the isotope, Lw^{257} , with a half-life of 8 seconds.

The heaviest elements of the periodic system with atomic numbers 89 (actinium) through 103 (lawrencium) are members of the actinide series, analogous to the lanthanide series or rare earths (atomic numbers 57 through 71). An inner electron shell, consisting of fourteen *5f* electrons is filled in progressing across the series.

Since the actinide series was completed with lawrencium, element 103, the succeeding elements yet to be discovered with atomic numbers 104 through 108 should be chemical homologs to the known elements with atomic numbers 72 (hafnium) to 76 (osmium). This analogy would continue in the still heavier transuranium elements, and element 118 would be a rare gas.

Chemically the present transuranium elements, which are all members of the actinide series, are very similar, although the observed differences are those expected and anticipated from their unique position in the periodic system as part of a second rare-earth series. All have trivalent ions, which form inorganic complex ions and organic chelates. Also in common are acid-insoluble trifluorides and oxalates, soluble sulfates, nitrates, chlorides, and perchlorates. Neptunium-plutonium and americium have higher oxidation states in aqueous solution (similar to uranium), but the relative stability of these states to the common trivalent ion becomes progressively less as one proceeds to the higher atomic numbers. This is a direct consequence, indeed an identifying feature, of the actinide role as a second rare-earth type transition series.

One of the most important methods for study and elucidation of chemical behavior of the actinide elements has been ion-exchange chroma-

tography. Adsorption on and elution from ion-exchange columns have made possible the identification and separation of trace quantities of all of the actinides and in particular the transuranium elements. The behavior of each actinide and transuranium element in this respect is very similar to its analogous rare-earth element. This has made it possible to detect as little as one or two atoms when this small a number has been made in some of the transmutation experiments.

The concept of atomic weight in the sense applied to naturally occurring elements is not applicable to the transuranium elements, since the isotopic composition of any given sample depends on its source. In most cases, the use of the mass number of the longest-lived isotope in combination with an evaluation of its availability has been adequate. Good choices at present are neptunium, 237; plutonium, 242; americium, 243; curium, 248; berkelium, 249; californium, 249; einsteinium, 254; and fermium, 255.

Brief descriptions of the transuranium elements follow:

Neptunium. Neptunium (Np, atomic number 93, after the planet Neptune). Neptunium was the first of the synthetic transuranium elements to be discovered; the isotope Np^{239} was produced by McMillan and Abelson in 1940 at Berkeley, California, as the result of the bombardment of uranium with cyclotron-produced neutrons. The isotope Np^{237} (half-life of 2.2×10^6 years) is currently obtained in kilogram quantities as a by-product from nuclear reactors in the production of plutonium. Trace quantities of the element are actually found in nature owing to transmutation reactions in uranium ores produced by the neutrons which are present.

Neptunium metal has a silvery appearance, is chemically reactive, melts at 640°C and exists in at least three structural modifications: α -neptunium, orthorhombic, density = 20.45 g/cm^3 ; β -neptunium (above 278°C), tetragonal, density (313°C) = 19.36 g/cm^3 ; γ -neptunium (above 500°C), cubic, density (600°C) = 18.0 g/cm^3 .

Neptunium gives rise to four ionic oxidation states in solution: Np^{+3} (pale purple), analogous to the rare earth ion Pm^{+3} , Np^{+4} (yellow green), NpO_2^+ (green blue), and NpO_2^{++} (pale pink). These latter oxygenated species are in contrast to the rare earths which exhibit only simple ions of the (II), (III), and (IV) oxidation states in aqueous solution. The element forms tri- and tetrahalides such as NpF_3 , NpF_4 , NpCl_4 , NpBr_3 , NpI_3 , and oxides of various compositions such as are found in the uranium-oxygen system, including Np_2O_7 and NpO_2 .

Plutonium. Plutonium (Pu, atomic number 94, after the planet Pluto). Plutonium was the second transuranium element to be discovered; the isotope Pu^{239} was produced in 1940 by Seaborg, McMillan, Kennedy, and Wahl at Berkeley, California, by deuteron bombardment of uranium in the 60-inch cyclotron. By far of greatest importance is the isotope Pu^{239} (half-life of 24,400 years) which is fissionable with thermal neutrons and produced in extensive quantities in

nuclear reactors from the abundant nonfissionable uranium isotope U^{238} :

Plutonium has assumed the position of dominant importance among the transuranium elements because of its successful use as an explosive ingredient in nuclear weapons and the place which it holds as a key material in the development of industrial utilization of nuclear energy, one pound being equivalent to about 10 000 kWh of heat energy. In certain nuclear reactors called breeder reactors, it is possible to create more new plutonium from U^{238} than plutonium consumed in sustaining the fission chain reaction. Because of this, plutonium is the key to unlocking the enormous energy reserves in the nonfissionable isotope U^{238} .

Plutonium also exists in trace quantities in naturally occurring uranium ores. It is formed in much the same manner as neptunium, by irradiation of natural uranium with the neutrons which are present.

Plutonium metal can be prepared, in common with neptunium and uranium, by reduction of the trifluoride with alkaline-earth metals. The metal has a silvery appearance, is chemically reactive, and melts at 640°C. It exhibits six crystalline modifications: α -plutonium, orthorhombic, below 122°C; β -plutonium, monoclinic, 122 to 206°C; γ -plutonium, 206 to 319°C; δ -plutonium, face-centered cubic, 319 to 451°C; δ' -plutonium, tetragonal, 451 to 476°C and ϵ -plutonium, body-centered cubic, 476°C up to the melting point.

Plutonium also exhibits four ionic valence states in aqueous solutions: Pu^{+3} (blue lavender), Pu^{+4} (color unknown), AmO_2^{+2} (light tan), and a fluoride complex of the +4 state. The trivalent state is highly stable and difficult to oxidize. AmO_2^{+2} , like plutonium, is unstable with respect to disproportionation into Am^{+3} and AmO_2^{+2} . The ion Am^{+4} may be stabilized in solution only in the presence of very high concentrations of fluoride ion, and tetravalent solid compounds are well known. There is some evidence that Am^{+2} has been prepared in tracer experiments at very low concentrations; this would be very similar to the analogous lanthanide, europium, which can be reduced to the divalent state.

Americium forms binary compounds with oxygen: PuO , PuO_2 , and intermediate oxides of variable composition; with the halides: PuF_3 , PuF_4 , $PuCl_3$, $PuBr_3$, PuI_3 ; with carbon, nitrogen and silicon; PuC , PuN , $PuSi_2$; in addition oxyhalides are well known: $PuOCl$, $PuOBr$, $PuOI$.

Because of the high rate of emission of alpha particles, and the physiological fact that the element is specifically absorbed by bone marrow, plutonium, as well as all of the other transuranium elements except neptunium, are radiological poisons and must be handled with special equipment and precautions.

Americium. Americium (Am, atomic number 95, after the Americas). Americium was the fourth transuranium element to be discovered; the isotope Am^{241} was identified by Seaborg, James, Morgan and Ghiorso late in 1944 at the wartime Metallurgical Laboratory (now the Argonne National Laboratory) of the University of Chicago as the result of successive neutron capture reac-

tions by plutonium isotopes in a nuclear reactor:

Americium is produced in kilogram quantities. Since the isotope Am^{241} can be prepared in relatively pure form by extraction as a decay product over a period of years from plutonium containing Pu^{241} , this isotope is used for much of the chemical investigation of this element. Better suited is the isotope Am^{243} owing to its longer half-life (8.8×10^3 years as compared to 470 years for Am^{241}). A mixture of the isotopes Am^{241} , Am^{242} , and Am^{243} can be prepared by intense neutron irradiation of Am^{241} according to the reactions $Am^{241}(n, \gamma) Am^{242}(n, \gamma) Am^{243}$. Nearly isotopically pure Am^{243} can be prepared by a sequence of neutron bombardments and chemical separations as follows: Neutron bombardment of Am^{241} yields Pu^{242} by the reactions $Am^{241}(n, \gamma) Am^{242} \xrightarrow{\beta^-} Pu^{242}$; after chemical separation the Pu^{242} can be transformed to Am^{243} via the reactions $Pu^{242}(n, \gamma) Pu^{243} \xrightarrow{\beta^-} Am^{243}$, and the Am^{243} can be chemically separated. Fairly pure Pu^{242} can be prepared more simply by very intense neutron irradiation of Pu^{239} as the result of successive neutron-capture reactions.

Americium can be obtained as a silvery white reactive metal by reduction of americium trifluoride with barium vapor at 1000 to 1200°C. It appears to be more malleable than uranium or neptunium and tarnishes slowly in dry air at room temperature. The density is 13.67 g/cm³ with a melting point at 994°C.

The element exists in four oxidation states in aqueous solution: Am^{+3} (light salmon), AmO_2^{+2} (color unknown), AmO_2^{+2} (light tan), and a fluoride complex of the +4 state. The trivalent state is highly stable and difficult to oxidize. AmO_2^{+2} , like plutonium, is unstable with respect to disproportionation into Am^{+3} and AmO_2^{+2} . The ion Am^{+4} may be stabilized in solution only in the presence of very high concentrations of fluoride ion, and tetravalent solid compounds are well known. There is some evidence that Am^{+2} has been prepared in tracer experiments at very low concentrations; this would be very similar to the analogous lanthanide, europium, which can be reduced to the divalent state.

Americium dioxide, AmO_2 , is the important oxide; Am_2O_3 and, as with previous actinide elements, oxides of variable composition between $AmO_{1.5}$ and AmO_2 are known. The halides AmF_3 , AmF_4 , $AmCl_3$, $AmBr_3$, and AmI_3 have also been prepared.

Curium. Curium (Cm, atomic number 96, after Pierre and Marie Curie). Although curium comes after americium in the periodic system, it was actually known before americium and was the third transuranium element to be discovered. It was identified by Seaborg, James and Ghiorso in the summer of 1944 at the wartime Metallurgical Laboratory in Chicago as a result of helium-ion bombardment of Pu^{239} in the Berkeley, California, 60-inch cyclotron. It is of special interest because it is in this element that the first

half of the transition series of actinide elements is completed.

The isotope Cm^{242} (half-life 162.5 days) produced from Am^{241} by the reactions $\text{Am}^{241}(n, \gamma) \text{Am}^{242} \xrightarrow{\beta^-} \text{Cm}^{242}$ has been used for much work with macroscopic quantities, although this is difficult due to the extremely high specific alpha activity. An excellent isotope for the investigation of curium in weighable amounts is Cm^{244} because it has a half-life of 19 years and can be prepared in fairly pure form by a sequence of neutron bombardments and chemical separations as follows. The neutron bombardment of Am^{241} yields Pu^{242} by the reactions $\text{Am}^{241}(n, \gamma) \text{Am}^{242} \xrightarrow{\beta^-} \text{Pu}^{242}$; after chemical separation the Pu^{242} can be transformed to Am^{243} via the reactions $\text{Pu}^{242}(n, \gamma) \text{Pu}^{243} \rightarrow \text{Am}^{243}$. Fairly pure Pu^{242} can be prepared more simply by very intense neutron irradiation of Pu^{239} as the result of successive neutron-capture reactions. The Am^{243} can be chemically separated and finally transmuted to Cm^{244} through neutron bombardment by the reactions $\text{Am}^{243}(n, \gamma) \text{Am}^{244} \rightarrow \text{Cm}^{244}$. Further neutron bombardment of Cm^{244} produces higher-mass isotopes of longer half-life which are even better for use in the investigation of curium.

Curium metal resembles americium metal in crystal structure but melts at the considerably higher temperature of 1340°C. It can be prepared by heating curium trifluoride with barium vapor at 1350°C.

The main oxidation state in aqueous solutions which has been definitely identified is Cm^{+3} , although a solid, black CmO_2 has been prepared. Cm_2O_3 and CmF_3 , both white compounds, have also been characterized. The general trend of decreasing stability of higher oxidation states with increasing atomic number would indicate that simple ions of curium higher than curium (III) will probably not be stable in aqueous solutions. It has further been demonstrated that curium (III) cannot be reduced in aqueous solutions.

The experimentally determined magnetic susceptibility of CmF_3 is in good agreement with the value expected for the electronic structure $5f^7$ in curium (III), assuming a Russell-Saunders coupling scheme.

Berkelium. Berkelium (Bk, atomic number 97, after Berkeley, California). Berkelium, the eighth member of the actinide transition series, was discovered in December, 1949, by Thompson, Ghiorso, and Seaborg and was the fifth transuranium element synthesized. It was produced by cyclotron bombardment of Am^{241} with helium ions at Berkeley, California.

The chemical properties of berkelium have been studied partly through the use of tracer amounts. The pale orange dioxide has been prepared by igniting the sulfate at 1200°C. These studies have demonstrated that berkelium exists in aqueous solutions in two oxidation states, berkelium (III) and berkelium (IV). The chemistry and solubility of compounds appears to closely follow the other transuranium elements.

The existence of Bk^{249} with a half-life of about

300 days makes it feasible to isolate berkelium in weighable amounts so that its properties can be investigated with macroscopic quantities. This isotope can be prepared by the intense neutron bombardment of Cm^{244} as the result of the capture of successive neutrons by the reactions $\text{Cm}^{244}(n, \gamma) \text{Cm}^{245}(n, \gamma) \text{Cm}^{246}(n, \gamma) \text{Cm}^{247}$

$(n, \gamma) \text{Cm}^{248}(n, \gamma) \text{Cm}^{249} \xrightarrow{\beta^-} \text{Bk}^{249}$.

Californium. Californium (Cf, atomic number 98, after the state and University of California). Californium, the sixth transuranium element to be discovered, was produced by Thompson, Street, Ghiorso, and Seaborg in January, 1950, by helium-ion bombardment of microgram quantities of Cm^{242} in the Berkeley 60-inch cyclotron. Californium (III) is the only ion stable in aqueous solutions, all attempts to reduce or oxidize californium (III) having failed. The existence of the isotopes of Cf^{249} , Cf^{250} , Cf^{251} , and Cf^{252} makes it feasible to isolate californium in weighable amounts so that its properties can be investigated with macroscopic quantities. Both the solid trichloride and oxychloride have been prepared. The isotope Cf^{249} results from the beta decay of Bk^{249} while the heavier isotopes are produced by intense neutron irradiation by the reactions $\text{Bk}^{249}(n, \gamma) \text{Bk}^{250} \xrightarrow{\beta^-} \text{Cf}^{250}$ and $\text{Cf}^{249}(n, \gamma) \text{Cf}^{250}$ followed by $\text{Cf}^{250}(n, \gamma) \text{Cf}^{251}(n, \gamma) \text{Cf}^{252}$.

Einsteinium. Einsteinium (Es, atomic number 99, after Albert Einstein). Einsteinium, the seventh transuranium element to be discovered, was identified by Ghiorso *et al.* in December, 1952, in the debris from a thermonuclear explosion in work involving the University of California Radiation Laboratory, the Argonne National Laboratory, and the Los Alamos Scientific Laboratory. The isotope produced was the 20-day Es^{253} , originating from beta decay of U^{253} and daughters. Its chemical properties have been studied solely with tracer amounts and indicate that the (III) oxidation state may be the only one which exists in aqueous solution. Existence of a relatively long-lived isomeric form of Es^{254} makes it possible to isolate this element in weighable amounts. The isotope Es^{253} and heavier isotopes can be produced by intense neutron irradiation of lower elements such as plutonium, by a process of successive neutron capture interspersed with beta decays until these mass numbers and atomic numbers are reached.

Fermium. Fermium (Fm, atomic number 100, after Enrico Fermi). Fermium, the eighth transuranium element to be discovered, was identified by Ghiorso *et al.* early in 1953 in the debris from a thermonuclear explosion in work involving the University of California Radiation Laboratory, the Argonne National Laboratory, and the Los Alamos Scientific Laboratory. The isotope produced was the 16-hour Fm^{255} , originating from the beta decay of U^{255} and daughters. Since this is the longest-lived presently known fermium isotope, it seems unlikely that this element can be isolated in weighable amount. Its chemical properties have been studied solely

with tracer amounts, and in normal aqueous media only the (III) oxidation state appears to exist. The isotope Fm^{254} and heavier isotopes can be produced by intense neutron irradiation of lower elements, such as plutonium, by a process of successive neutron capture interspersed with beta decays until these mass numbers and atomic numbers are reached.

Mendelevium. Mendelevium (Md, atomic number 101, after Dmitri Mendeleev). Mendelevium, the ninth transuranium element to be discovered, was first identified by Ghiorso, Harvey, Choppin, Thompson, and Seaborg in early 1955 as a result of the bombardment of the isotope Es^{253} with helium ions in the Berkeley 60-inch cyclotron. The isotope produced was presumably Md^{256} which apparently decays by electron capture to Fm^{256} , which in turn decays predominantly by spontaneous fission with a half-life of about 3 hours. This first identification was notable in that only of the order of one to three atoms per experiment were produced. The extreme sensitivity for detection depended on the fact that its chemical properties could be accurately predicted as *eka-thulium* and there was a high sensitivity for detection because of the spontaneous fission decay. The chemical properties have been investigated solely by the tracer technique and seem to indicate that the predominant oxidation state in aqueous solution is the (III) state. There seem to be no isotopes of sufficiently long half-life to make it possible to isolate this element in weighable quantity.

Element 102. An isotope of element 102, 102^{254} with a half-life of about 3 seconds, was discovered by Ghiorso, T. Sikkeland, J. R. Walton, and Seaborg at the University of California in Berkeley in 1958. The element was produced by the bombardment of Cm^{246} with C^{12} ions accelerated in the heavy ion linear accelerator. The isotope was identified through chemical identification of the known daughter Fm^{250} , which was separated by a recoil technique from its alpha-decaying parent.

Earlier in 1957, a team of scientists from the United States, England and Sweden announced the apparent discovery of an isotope of element 102 as a result of research performed at the Nobel Institute for Physics in Stockholm. The name nobelium was suggested by this group for element 102. However, neither experiments at the University of California in Berkeley, which were more sensitive than the Stockholm work, nor related experiments performed in the USSR, have confirmed this apparently erroneous discovery. Although the name nobelium for element 102 will undoubtedly have to be rejected, no suggestion for a new name has yet been made.

Lawrencium. Lawrencium (Lw, atomic number 103, after Ernest O. Lawrence). Lawrencium was discovered in 1961 by A. Ghiorso, T. Sikkeland, A. E. Larsh, and R. M. Latimer using the heavy-ion linear accelerator at the University of California at Berkeley. A few micrograms of a mixture of Cf^{249} , Cf^{250} , Cf^{251} , and Cf^{252} were bombarded with B^{10} and B^{11} ions to produce Lw^{257} which has a

half-life of 8 seconds. It was determined that this isotope decays by the emission of an 8.6-MeV alpha particle.

At present, because of the short half-life of lawrencium, it has not been possible to perform a chemical identification and the discovery rests on nuclear evidence. Lawrencium is the fourteenth and last member of the actinide series and therefore should be chemically similar to the lighter transuranium elements.

TUNNELING

Tunneling is a quantum mechanical process without a classical analog. An electron (or other quantum mechanical particle) incident upon a potential barrier whose height is larger than the kinetic energy of the electron will penetrate (tunnel) a certain distance into the barrier. This is most easily visualized by considering the one-dimensional Schrödinger equation for the wave function $\psi(x)$ of such an electron:

$$-\frac{\hbar^2}{2m} \frac{\partial^2 \psi}{\partial x^2} + V(x)\psi = E\psi \quad (1)$$

If V varies relatively slowly with distance, the solution of Eq. (1) can be approximated by

$$\psi \approx \psi_0 \exp \left[\pm i \frac{\sqrt{2m}}{\hbar} \int \sqrt{V(x) - E} dx \right] \quad (2)$$

The non classical case is the one where the electron energy E is smaller than the potential $V(x)$. Then ψ is no longer an oscillating wave, but it is real and decays exponentially with distance into the barrier. The penetration probability through a given barrier is equal to the ratio of the probability density $|\psi(x)|^2$ at the exit from the barrier to its value at the entrance. Equation (2) shows that this probability is exponentially dependent on barrier height and thickness. The tunneling takes place at constant electron energy as there is no scattering involved.

A more accurate solution of Eq. (1), which adequately described many real situations, may be calculated by the Wentzel, Kramers, Brillouin (WKB) approximation. The tunneling probability through a barrier then becomes

$$P \approx \exp \left[-2 \int_{x_1}^{x_2} \frac{\sqrt{2m}}{\hbar} \sqrt{V(x) - E} dx \right] \quad (3)$$

An idea of the magnitude of the tunneling probability may be obtained by calculating the value of Eq. (3) for a rectangular barrier 1 eV higher than the particle energy and 25 Å wide. The result for an electron is $P \approx 10^{-11}$; for a proton, $P \approx 10^{-400}$.

Tunneling can occur in many physical situations. The simplest case is that of FIELD EMISSION.

This is the emission of electrons from a solid by the application of very high fields. The energy-band diagram for such a system is shown in Fig. 1.

FIG. 1. Simplified energy-band diagram for field emission from a metal. $\psi(x)$ represents the wave function of an electron with energy E .

The electrons in a metal surrounded by vacuum can be regarded as an ensemble of quasi-free electrons held in a potential well by the positive charges of the metal ions. The depth of the well is called the electron affinity χ . The potential well is filled with electrons up to the Fermi level (E_F) and consequently electrons at this level "see" a barrier $\phi_M = \chi - E_F$ (work function) surrounding them. They can tunnel a short distance into the walls of the potential well, but of course cannot escape from it.

If a high positive field ξ is applied to the metal (e.g., by applying a potential difference between the metal under consideration and an adjacent piece of metal), the potential energy distribution is that shown in the Figure. There now exists a barrier through which, under appropriate conditions, the electrons may tunnel. The minimum height of the barrier is ϕ_M , and its width is approximately $\frac{\phi_M}{\xi}$ so that the current becomes

$$I \propto P \approx \exp \left[-2 \frac{2}{3} \frac{\sqrt{2m}}{\hbar} \sqrt{\phi_M} \frac{\phi_M}{\xi} \right] \approx \exp \left[-10^8 \frac{\phi_M^2}{\xi} \right] \quad (4)$$

if ϕ_M is given in units of electron volts and ξ in units of volts per centimeter. Since ϕ_M generally has a value between 2 and 5 eV, an electric field of the order of 10^7 volts/cm is required before appreciable numbers of electrons will be emitted into vacuum.

Figure 1 is a somewhat simplified picture of an actual metal-vacuum interface. An electron outside the metal experiences a polarization force towards the metal, the so-called image force. While this is not a true potential, it may nevertheless be included in the potential energy diagram as a rounding-off of the well edge. When the field is applied, this will mean that the barrier is lowered and so the tunneling probability is increased.

Particularly at high fields this will cause a departure from the simple current relationship described above. If these effects are included in the calculation, good agreement can be obtained with experimental results.

Current flow at a metal-insulator interface may be treated in the same way as that at a metal-vacuum boundary. The potential barrier height is now given by the distance from the metal Fermi level to the bottom of the insulator conduction band, which is usually smaller than the work function. Also the dielectric constant of the insulator will have to be taken into account (e.g., in the image force). These modifications do not change the basic current-voltage relationship [Eq. (4)] which has also been verified experimentally.

In case of a very thin insulator layer ($\sim 60\text{\AA}$) bounded on both sides by metallic regions, high fields are no longer required for tunneling. The band structure may be approximated by the square potential barrier discussed initially. The top of the barrier is again formed by the conduction band of the insulator, modified appropriately by image force considerations. In equilibrium, there will be equal numbers of electrons tunneling in both directions through the insulator; no net current flows.

When a potential difference is applied, one tunneling direction is favored and net current flows. For small potential differences (much less than the barrier heights) the tunneling probability does not vary with applied field and the current flowing will be proportional to the difference in number of electrons available on the two sides of the barrier at the same energies. These numbers are in turn closely related to the density of electronic states in the metals at these energies. The tunneling current may therefore be used to investigate the density of states in certain materials, where this quantity changes rapidly with energy.

This technique for determining the density of states has been put to particularly good use in the case of superconductors. The fact that the superconductor has an energy gap in the density-of-states function at the Fermi level leads to nonlinearities and negative resistance regions in the current-voltage characteristics. This has become the most accurate method of measuring the energy gap of superconductors as a function of temperature, magnetic field and other variables. More complicated phenomena, such as simultaneous tunneling of two electrons as a pair, have also been observed.

Tunneling out of a three-dimensional well is treated similarly to tunneling through the one-dimensional barrier. The exact exponential dependence will be different from Eq. (2) and depend on the form of the barrier. One type of three-dimensional well is formed by an impurity in a semiconductor or insulator which may form a bound state in the region of the forbidden gap. An electron can only tunnel out of such a state when a high field is applied, analogous to field emission from metals.

A different type of three-dimensional potential

well is found in the atomic nucleus. A combination of short-range nuclear attraction and Coulomb repulsion forms a potential barrier of the type shown in Fig. 2. Many heavy radioactive nuclei contain α -particles with high enough kinetic energy to tunnel through the barrier (α -decay). Because of the much heavier mass and high barrier energy, the barrier must be considerably thinner than for an electron ($\sim 10^{-12}$ cm). Again calculations for a Coulomb barrier agree well with experimental observations of the energy dependence of the decay time (Geiger-Nuttall relation).

Electron tunneling is also observed in semiconductors (Zener tunneling), but in this case the situation cannot be represented by the kind of barrier discussed previously. The band structure of a semiconductor under a large applied field is shown in Fig. 3. There exists no set of real energy states connecting the two regions, and an electron must always make a discontinuous step in passing from the valence band to the conduction band. Still the tunneling probability may be calculated with an approximation equivalent to that used for the simple barrier, and except for a numerical factor, the result is the same as Eq. (4) with ϕ_M replaced by E_g .

FIG. 2. Model of the nucleus, with $\psi(r)$ the wave function of an α -particle.

FIG. 3. Band structure of a semiconductor or insulator under an applied field.

Conduction of this type is observed in very narrow p - n junctions under reverse bias (Zener breakdown) or in insulators where there are no free carriers available. In the former case, there is a large built-in field even at zero external voltage which is produced by the difference in the electrochemical potentials of the n - and p -regions. A small additional voltage (1 to 2 volts) raises the field to the value required for tunneling.

In still narrower p - n junctions ("tunnel diodes") tunneling readily takes place even where no applied voltage exists. As in the case of the very thin insulator, the electrons tunneling in opposite

directions then just cancel one another out. The current-voltage curve of such a junction is drawn in Fig. 4. The band structure configurations at two values of forward bias are also shown. Net

FIG. 4. Current-voltage characteristic of a tunnel diode. The two inserts depict the band structure at the maximum tunnel current and at the valley where tunneling is no longer possible.

tunneling current will flow in either direction of applied voltage, as long as there are electrons on one side opposite empty states of the same energy on the other side. Under large forward current this condition is no longer fulfilled, as the bottom of the conduction band on the n -type side comes opposite the forbidden energy gap on the p -type side. This means that the current passes through a maximum value and then decreases towards zero with increasing forward bias. In actual diodes, the current never decreases completely to zero since the electrons can interact with impurity states in the forbidden gap, dissipating their excess energy so they can drop into the valence band states on the p -type side. At still larger bias, the conventional forward diode current becomes dominating.

U

ULTRASONICS

Ultrasonic Waves. Ultrasonic waves are sound waves above the frequency normally detectable by the human ear, that is above about 20 kc/sec. The particles of matter transmitting a *longitudinal* wave move back and forward about mean positions in a direction parallel to the path of the wave. Alternate compressions and rarefactions in the transmitting material exist along the wave propagation direction. In *shear* waves, the particles move perpendicularly to the direction of wave propagation. In surface waves in seismological studies and in waves through thin stock, the *Rayleigh* and *Lamb* waves respectively, the particles undergo much more complicated vibratory motions than in longitudinal and transverse waves (see WAVE MOTION).

TABLE 1. APPROXIMATE SOUND VELOCITIES

	In Water (m/sec)	In Steel (m/sec)
Longitudinal	1.5×10^3	6×10^3
Transverse	Cannot be supported	3×10^3
Rayleigh	..	3×10^3

In most practical applications of ultrasonics, pulses or packets containing a number of oscillation cycles are sent through the solid or liquid under investigation. A longitudinal wave pulse, when incident on the boundary between two materials having different sound velocities, is transformed into reflected and refracted shear and longitudinal waves. Snell's law governs the angles of REFLECTION and REFRACTION for both types of waves. It states that

$$\frac{\sin \theta}{V} = \text{Constant}$$

where θ is the angle the beam makes with a normal to the intervening surface and V is the sound velocity. Therefore, in Fig. 1,

$$\text{Constant} = \frac{\sin \theta_1}{V_{L1}} = \frac{\sin \theta_2}{V_{L2}} = \frac{\sin \phi_1}{V_{S1}} = \frac{\sin \phi_2}{V_{S2}}$$

Transducers. In general, a transducer is a device to convert electrical energy into mechanical vibrations which are then directed into the specimen. The transducer also commonly reconverts received mechanical oscillations back again into

electrical signals for amplification and recognition. Transducers are usually piezoelectric, ferroelectric or magnetostrictive in nature.

The application of a voltage across a piezoelectric crystal causes it to deform with an amplitude of deformation proportional to the voltage. Reversal of the voltage causes reversal of the mechanical strain. Until recently, the only piezoelectric transducer in general use was quartz, but now several synthetic ceramic materials are employed.

FIG. 1.

Ferroelectric crystals are also electrostrictive. Barium titanate has an electrical mechanical conversion efficiency about one hundred times that of quartz. Unlike the piezoelectric mode of oscillation, in ferroelectric crystals application of a voltage in either direction across the crystal causes expansion of the crystal. This mode can however be converted to the piezoelectric by biasing the expansion in one direction either by application of a strong dc field or more commonly by cooling the ferroelectric crystal through its Curie temperature while it is under the influence of a strong electric field (order of 10^6 volts/m).

Transducer crystals are normally cut to a resonant frequency, the thickness being one-half the acoustic wavelength. A bond between the crystal transducer and the specimen matches the acoustic impedance and carries the acoustic power into the latter. Backing layers may be fixed to the rear surface of the transducer. These layers are chosen to reflect power forward into

the crystal and specimen in some technological applications. They may also be chosen to absorb power so as not to complicate signals received in material testing applications.

Ultrasonic Testing. Most ultrasonic test equipment employs pulses of high-frequency sound (>1 Mc/sec), the pulse width being adjustable between 0.1 and 1.0 μ sec and the repetition rate between 60 and 1000 pulses per second. Figure 2 shows a typical block diagram.

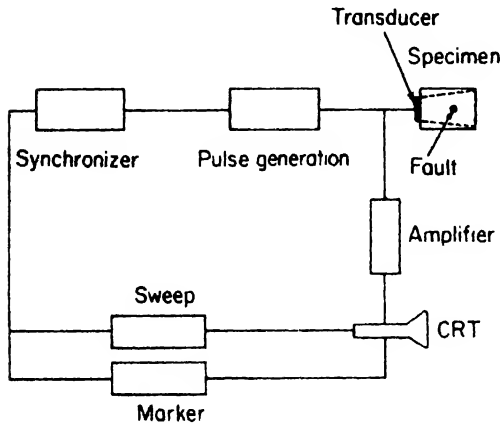

FIG. 2.

The synchronizer triggers a pulse in the generation circuit. This is converted to an acoustic pulse by the transducer crystal. The synchronizer also starts the sweep circuit of the cathode ray tube (CRT) and the marker circuit, the latter making marker pips along the time base. Separate transducer crystals may be used for transmission and reflection, or one crystal may be made to carry out both functions. The echo from the back face of the specimen block arrives twice the transmission time after the initial pulse. The marker pips can then be calibrated in depth. A fault will show up as an extra echo whose depth into the specimen can be read from the marker pip which coincides with its position on the screen of the CRT.

The transducer is coupled to the specimen under test by an oil or adhesive. In high-speed testing or in cases where rough surfaces are encountered, the specimen may be immersed in a liquid or a stream of liquid passed between the transducer and the specimen in order to give sonic coupling.

Examples of Ultrasonic Testing. Solid objects of thickness greater than about half an inch may be tested for inhomogeneities. Special techniques also exist for sheet testing. Heavy forgings, crank shafts, rails, concrete structures and a host of other manufactured objects are now regularly scanned for porosity or internal faults. The frequencies employed are normally from 1 to 5 Mc/sec for steel objects, about 0.5 Mc/sec for many plastics and 0.1 Mc/sec for concrete.

In a medical application of ultrasonic techniques, the subject is immersed in water and the

transducer is scanned in a circular path round the axis of the torso or limb under detailed examination. Echoes are recorded on the CRT which is also circularly scanned (like the P.P.I. radar system). A long persistence screen gives a complete record of the scanned portion of the body. Gallstones, tumors, cancers and other pathological conditions are revealed.

Sophisticated scanning arrays are used in SONAR underwater detection. Frequencies must be low because of the high attenuation in water (at 100 kc/sec attenuation ≈ 60 decibels/km), and this limits definition. Sea noises, fish and underwater refraction by layers at different temperatures introduce difficulty of interpretation into the echo patterns. Depth recording is now accomplished by the use of many sending and receiving transducers coupled to a computing system which interprets differences of arrival times in terms of variation of path length and ultimately of depth. Continuous records of the ocean bed or the depth of surface ice can be made.

Systems similar in principle to Sonar are also employed to give continuous records of manufactured plate thickness and to control the filling of enclosed tanks.

Examples of the Use of Ultrasonic Power. Longitudinal ultrasonic waves can be produced at sufficient intensity to cause changes in materials of industrial importance. In many cases, standing waves are set up in a containing vessel with resulting periodic variation of vibration amplitude. In almost all cases ceramic transducers are used. Emulsifying, mixing, dispersing, degassing and cleaning applications generally employ unfocused acoustic radiation. In welding, soldering, drilling, machining and the neurosurgical controlled damage of brain tissue, on the other hand, a focused acoustic beam is always used.

Focusing may be done by the use of either an acoustic horn or by an acoustic lens. Figure 3

FIG. 3.

shows the principle of a simple plano-concave lens whose radius of curvature r is given by

$$r = f \left(\frac{n-1}{n} \right)$$

where n , the index of refraction, is the ratio of the velocities in the lens and adjacent medium:

$$n = \frac{V_1}{V_2}$$

Fundamental research in physics by ultrasonics. *Acoustic Velocity.* The acoustic velocity in a material is fundamentally related to the binding

forces between the atoms or molecules. Measurement of the velocity is made by a pulse technique or by vibrating a specimen of known dimensions in one of its fundamental modes of oscillation and recording the frequency.

Acoustic Attenuation. Attenuation measurements are made by recording the decay in oscillation amplitude with time of a solid material set to ring in one of its natural modes. Attenuation may also be measured from the amplitude of successive echoes passing through the material.

Under the influence of thermal activation, impurity elements or defects may switch position in a crystal lattice. This they do in a definite RELAXATION time, which is related exponentially to the temperature and to the difference in energy of the defect in its two positions. Now if the switching of position of the defect also causes a difference in dimension of the specimen, then a maximum in attenuation is found when the period of an applied acoustic stress just matches the thermal relaxation time. A whole spectrum of relaxation attenuation maxima have been found in solids. Each is related to a definite internal process, each with its characteristic energy difference. Perhaps the best known of these is the relaxation maximum given by the diffusion of carbon atoms in iron from which the activation energy for carbon diffusion can be calculated (Snoek peaks).

Dislocations are line defects in crystalline material the movement of which is involved in all cases of plastic deformation. Acoustic waves vibrate the dislocations, and in general, the more freely the dislocation moves, the greater is the acoustic beam attenuated. Attenuation measurements thus give information on how well the dislocation is locked in position in the solid, i.e., on how strong the material is. Pinning down of the dislocations may be effected by alloying or by radiation with high-energy particles which cause internal damage. Measurement of acoustic attenuation is therefore encountered in such studies.

Electrons in metals also attenuate acoustic waves if the frequencies are sufficiently high (>5 Mc/sec) and the temperature sufficiently low ($<10^\circ\text{K}$) so that the acoustic wavelength is comparable with the mean free path of the electrons. Attenuation measurements give information on relaxation times of electrons, and hence their energies, and are therefore concerned in the study of Fermi surfaces in metals. Such studies are intimately related to the phenomena of electrical and heat conductivity.

The onset of superconductivity in some metals and alloys at low temperatures is characterized by a fall to zero electrical resistance and also by a sharp fall in high-frequency acoustic attenuation.

In nonmetallic crystalline materials, thermal vibrations or PHONONS interact with one another and limit heat conductivity. Measurements of high-frequency attenuation is now giving information on phonon-phonon interactions. Such information may lead to the elucidation of the spectrum of thermal vibrations in all materials above the absolute zero of temperature.

ULTRAVIOLET RADIATION

Ultraviolet radiation comprises the region of the electromagnetic spectrum extending from the violet end of the visible, wavelength 4000\AA , to the beginning of X-RAYS, arbitrarily taken as 100\AA , a span of more than five octaves. The unit of wavelength generally used for the ultraviolet is $\text{\AA} = 10^{-8}$ cm; it is named after A. J. Ångström, Swedish pioneer in SPECTROSCOPY, who made in 1868 the first accurate measurements of the wavelengths of spectral lines. Although still occasionally heard, the term ultraviolet rays has become obsolete. Ultraviolet light, however, is an expression which is usually acceptable even though ultraviolet cannot ordinarily be seen by the eye.

The ultraviolet is subdivided into several parts: The near ultraviolet, 4000 to 3000\AA , present in sunlight, producing important biological effects, but not detectable by the eye; the middle ultraviolet, 3000 to 2000\AA , called by biologists the far ultraviolet, not present in sunlight as it reaches the earth's surface, but well transmitted through air; the long range 2000 to 100\AA known as the extreme ultraviolet, abbreviated XUV, since it connects the ultraviolet and x-rays. The XUV is known also as the vacuum ultraviolet, because it is not transmitted through air, and is sometimes called the far ultraviolet. The portion of the XUV from 2000 to 1350\AA is known as the Schumann region, after its discoverer.

The boundary, 100\AA , between XUV and x-rays is arbitrary; it is often preferred to make the distinction on the basis of the method of production and analysis. Radiation is called x-rays if produced by the classical x-ray tube in which bombardment by electrons removes inner-shell electrons from atoms of the target material, with radiation emitted when outer electrons fall back; x-rays are also generated by the BREMSSTRAHLUNG process when fast electrons are suddenly decelerated. In sparks, arcs, and electrical discharges through gases, the classical sources of ultraviolet, it is the outer electrons of either neutral atoms or ions that are excited; the radiation occurs when the outer electrons are recaptured and fall back to their ground states (see ELECTRICAL DISCHARGES IN GASES).

Ultraviolet radiation was discovered by Ritter in 1801; he found that silver chloride was blackened, as it is by visible light, if placed beyond the violet end of the sun's spectrum, where nothing can be seen. Stokes, in 1862, using a prism of quartz rather than glass, observed to a short-wavelength limit of 1830\AA radiation produced by a spark discharge between aluminum electrodes by using a fluorescent plate detector. The breakthrough further into the ultraviolet was made between 1885 and 1903 by Victor Schumann, an instrument maker and machine shop owner of Leipzig. Schumann realized that there are three reasons why ultraviolet of shorter wavelengths had not been detected: (1) air is opaque, (2) quartz prisms and lenses do not transmit, (3) ordinary photographic emulsions are not sensitive, because of absorption by gelatin. He overcame these difficulties by constructing the first vacuum spectrograph, using optics of crystal fluorite instead of quartz, and by making photographic plates with almost no gelatin, now known as Schumann plates. Theodore Lyman of Harvard University, soon passed the limit, 1300\AA , reached by Schumann, by constructing a vacuum spectrograph with a reflection-type concave diffraction grating instead of the fluorite prism and lenses. He discovered the Lyman series of hydrogen, the most fundamental spectral series of the simplest and most abundant element, with first line, Lyman-alpha, at 1215.67\AA and series limit at 911.7\AA . Further progress reaching 140\AA was made by R. A. Millikan and his students at the California Institute of Technology with the aid of a "hot" spark in vacuum. Finally Osgood, in 1927, closed the gap to x-rays by combining the hot spark and a grating used at grating incidence; in the same year, Dauvillier reached 121\AA in the XUV from the x-ray side, using an x-ray tube with a spectrometer utilizing a crystal of large lattice constant, made from a fatty acid.

Ultraviolet radiation is emitted by almost all light sources, to some extent. In general, the higher the temperature, or the more energetic the excitation, the shorter are the wavelengths. Tungsten lamps in quartz envelopes radiate in the ultraviolet in accordance with Planck's law, slightly modified by the emissivity function of tungsten. Because of its high temperature, 3800°K , the crater of an open carbon arc is an excellent source of ultraviolet extending to the air cutoff. Electrical discharges through gases produce intense ultraviolet emission, mainly in lines and bands. The most widely used is the quartz mercury arc; when the Hg pressure is allowed to rise to several atmospheres, the intensity becomes great, and the spectrum is a quasi continuum. For the shortest wavelengths, still higher temperatures are required, as produced by discharging a large capacitor at some 50 kV between metal electrodes in vacuum. This violent discharge vaporizes atoms from the electrodes, then strips off as many as 10 or 15 outer electrons. The emission line radiation emitted when these highly ionized atoms recapture electrons extends to very short wavelengths. Another source producing highly ionized

atoms and emission lines in the XUV is the magnetically compressed plasma such as produced by the devices known as zeta and theta pinch, which reaches a temperature of half a million degrees. Still another useful source is the synchrotron, in which electrons are accelerated in circular paths through several hundred MeV. The electromagnetic radiation produced by the great centripetal acceleration is a continuum whose peak lies well below 100\AA . For great XUV intensity, however, no man-made source has equaled the atomic bomb.

Solids, liquids, and gases usually transmit well in the near ultraviolet but always become opaque somewhere in the middle or extreme ultraviolet. Among solids, both crystal and fused quartz transmit to a short wavelength limit between 2000 and 1500\AA , depending on purity; CaF_2 (fluorite), to 1230\AA ; and LiF , the most transparent known solid, to 1050\AA . These materials are invaluable for constructing lenses and prisms for ultraviolet instruments.

Solids in the form of very thin films transmit to some extent throughout the XUV, but the thickness must be less than a few thousand Ångströms. Certain thin films are useful as optical filters; Al, for example transmits from 837\AA corresponding to its plasmon frequency, to its x-ray L-edge at 170\AA , and to a small extent as far as 150\AA . Films of plastics, such as collodion of 300\AA thickness, transmit fairly well below 500\AA ; they are useful as windows for low-pressure gas retention.

Gases vary greatly in their absorption characteristics. Molecular oxygen causes air to become opaque below about 1850\AA , because of absorption in the Schumann-Runge band system, followed by continuous absorption from 1750 to 1290\AA , and strong irregular absorption to shorter wavelengths. Molecular nitrogen, however, is relatively transparent all the way to 1000\AA . Hydrogen absorbs in the Lyman series lines, and in an ionization continuum beyond the series limit, 911.7\AA . Of all the gases, helium is the most transparent; absorption first takes place in the resonance lines, the longest lying at 584\AA , and in a continuum beyond the series limit, 504\AA . More complicated molecular gases, such as CO_2 , NO, and N_2O are rather opaque throughout most of the XUV. Water vapor is much like O_2 with absorption commencing below 1850\AA .

Reflection occurs for ultraviolet, just as for visible radiation. In general, the reflectance becomes less, as the wavelength decreases. Aluminum is the best reflector over much of the long-wavelength region; when properly prepared, by rapid evaporation of the pure material in an excellent vacuum, the reflectance is greater than 90 per cent to 2000\AA , and can be maintained to 80 per cent at 1200\AA by overcoating with a thin layer of MgF_2 to prevent growth of Al_2O_3 . Below 1000\AA , platinum is best with a reflectance of about 20 per cent at 600\AA , but only about 4 per cent at 300\AA .

Ultraviolet can be detected in a variety of ways, making use of effects produced when it is absorbed by matter, e.g., fluorescence with reradiation of

longer wavelengths; chemical reactions in solids; dissociation of gas molecules, with ensuing reactions; ionization of gases; emission of photoelectrons from surfaces of solids. In general, the shorter the wavelength, the more energetic is the reaction. This is in accordance with Einstein's law, $E = h\nu$, giving the energy of a photon in terms of Planck's constant, h , and its frequency ν , (velocity of light \div wavelength). Thus, ultraviolet photons range up to about 10,000 times more energetic than visible photons, and effects produced by them are much easier to observe.

The simplest way to detect and measure ultraviolet radiation is by making use of the fluorescence process, converting the ultraviolet into visible radiation which can be seen, or into near ultraviolet which is easily photographed or measured with conventional photomultipliers. Calcium tungstate, for example, is an excellent converter for the middle ultraviolet. Materials much used for the extreme ultraviolet are oil and sodium salicylate. The latter is especially valuable because its quantum efficiency of fluorescence is high and is nearly independent of wavelength. An ordinary photomultiplier, with its glass window coated with a layer of sodium salicylate becomes a sensitive radiometer for use throughout the entire ultraviolet.

Ordinary photographic emulsions containing gelatin as a binder are useful only to about 2500Å; they can be sensitized easily by overcoating with oil or sodium salicylate. Eastman Kodak spectroscopic-type plates and films are available with ultraviolet sensitization, produced by overcoating with a fluorescent lacquer. Nearly gelatin-free Schumann-type emulsions combine greater sensitivity and higher resolving power than fluorescence-sensitized emulsions; they are available as Eastman Kodak SWR and SC-5, but must be handled carefully to avoid damaging the delicate surface.

Ultraviolet radiation is easily detected and measured directly by means of photomultipliers if they are equipped with ultraviolet transmitting windows or are used without an envelope in a vacuum. Almost all materials emit photoelectrons to some extent when ultraviolet-irradiated, but in applications, the problem is usually to devise a photocathode surface that has extremely high efficiency in a certain spectral region and is insensitive in others. When constructed with ultraviolet-transmitting envelopes, the various visible-sensitive photocathodes respond well throughout the ultraviolet. For applications in the presence of sunlight, however, it is often necessary to use a "solar blind" surface, having negligible sensitivity longward of 2900Å; one of the best surfaces is RbTe, with quantum efficiency of $< 10^{-3}$ at $\lambda > 3000\text{Å}$ and ≈ 0.1 at $\lambda < 2600\text{Å}$.

For use at wavelengths shorter than 1300Å the best photocathodes are simple metal surfaces, such as tungsten, used directly in vacuum. Most metals exhibit a strong internal photoelectric effect at $\lambda < 1500\text{Å}$, which reaches a high value of about 15 per cent at 1000Å. This high work function results in low sensitivity to long-wavelength

stray light, and low noise. Metal photocathodes are available in electrostatically focused photomultipliers with photocathode and dynodes of Be-Cu or stainless steel, and magnetically focused strip-photomultipliers with tungsten photocathodes. The sensitivity is little changed by repeated exposure to air.

Ionization chambers and Geiger counters form another useful class of detector of XUV radiation. Knowledge of the ionization efficiency of the gas makes it possible to use them for measurement of absolute energy. One of the most useful is filled with NO, responding from the ionization limit, 1350Å, to the transmission limit of the LiF window, 1050Å. To shorter wavelengths, it is possible to use Geiger counters without a window, by maintaining a slight positive gas pressure inside the tube. When filled with a rare gas, they count all incident photons of wavelengths shorter than the ionization limit of gas, since the gas ionization efficiency is 100 per cent.

Ultraviolet radiation can, of course, be detected with a thermocouple, by direct conversion of its energy into heat. Because of low sensitivity, this fundamental absolute method of energy measurement is resorted to only when no other method is available, for example, in order to establish that the ionization efficiency of the rare gases is 100 per cent for radiation below their series limits.

Mankind's principal source of energy, the sun, emits strongly throughout the ultraviolet, but only the near ultraviolet reaches the surface of the earth. Wavelengths shorter than 2900Å are absorbed by a layer of ozone (O_3) with center at an altitude of about fifteen miles.

The principal action of solar ultraviolet is to produce sunburn, or erythema, but it is only the shortest wavelengths penetrating the ozone layer which have this action. Since the effective band is centered at 2967Å and extends to about 3100Å, sunlight becomes rapidly more effective in burning the skin when the subject goes to a high altitude and when the sun lies high in the sky. Excessive exposure is known to be a cause of skin cancer.

The normal eye does not sense the sun's ultraviolet, although it does have a small sensitivity below 4000Å. Young eyes transmit more than old, and do, indeed, detect ultraviolet from 4000Å to about 3130Å as a faint, bluish sensation, but sharp images are not formed without special corrective lenses, on account of the chromatic aberration of the eye's optical system. To shorter wavelengths, ultraviolet is absorbed by the cornea and causes fluorescence, which is seen as a general haze. Excessive exposure to wavelengths short of 3000Å, however, causes conjunctivitis, a painful burn of the cornea. For this reason, it is extremely important to wear glass goggles, when in the presence of intense sources of middle ultraviolet radiation. Similarly, on snowfields and glaciers, goggles must be worn to prevent the form of conjunctivitis known as snow blindness.

A new and unfortunate action of solar ultraviolet is the production of Los Angeles-type smog, containing molecules which irritate the eye

and causes damage to plants. The photochemical processes are complicated and are not as yet completely understood. It is well established, however, that the principal atmospheric contaminants involved are nitrogen oxide, nitrogen dioxide, and various organic molecules present in gasoline engine exhausts. The initial process appears to be the absorption of solar ultraviolet by NO_2 , which produces O and NO. The principal reactions, however, are the photolysis of mixtures of nitrogen oxides and hydrocarbons in air, caused by absorption of solar ultraviolet. The products of the reactions are ozone, aldehydes, acrolein, acetone, and peroxyacyl nitrates and nitrites (PAN); among these, formaldehyde, acrolein, and PAN are specific eye irritants. One principal phytotoxicant is ozone, which produces a mottling or bleaching of the upper surfaces of leaves; various others cause a bronzing or glazing of the underneath surfaces of leaves. Obviously, solar ultraviolet cannot be eliminated; photochemical smog relief must come from the chemist.

The principal present-day application of ultraviolet radiation is in increasing the efficiency of conversion of electrical energy into light. The fluorescent lamp utilizes a coating of a crystalline substance, such as manganese-activated zinc silicate, on the inside wall of a mercury arc lamp, to convert the middle- and near-ultraviolet radiation from the mercury vapor column into visible light and thus add to the visible-line spectrum emission of the mercury. The efficiency of fluorescent lamps may reach values 2.5 times greater than those of commonly used incandescent tungsten lamps.

Another widespread use of ultraviolet is in "black lighting," largely for the theater. By introducing an ultraviolet-transmitting, visible-opaque filter over a carbon arc projector, an intense ultraviolet beam can be projected onto the stage. There it causes different materials to glow brilliantly, with color determined by the particular dye molecule.

As a technical industrial tool, ultraviolet spectroscopic analysis has become of extreme importance. In the production of steel, for example, a sample can be analyzed in minutes, by introducing it into a source electrode, and analyzing the radiation with a multichannel spectrometer. Different exit slits select the strongest and most sensitive emission lines of the various elements present; with photomultipliers, their intensities are measured and converted at once to give the composition of the steel.

Among various biological and medical applica-

tions of middle-ultraviolet radiation, perhaps the most important are its uses to kill bacteria and fungi in hospitals and especially in operating rooms, to eliminate the hepatitis virus from blood plasma, to keep foods sterile, and to treat skin diseases. Rickets and certain other diseases, can be cured by exposure of the body to ultraviolet, which produces vitamin D. Similarly, vitamin D is produced in milk by ultraviolet irradiation.

The middle- and extreme-ultraviolet radiation from the sun, although not able to reach the earth's surface, nevertheless affects man and his activities through its powerful influence on the upper atmosphere. First knowledge of the sun's ultraviolet spectrum was obtained in 1946, when a spectrograph was flown in a V-2 rocket by the U.S. Naval Research Laboratory and the solar spectrum was recorded from 3000 to 2200 Å. In the two decades since this event, great progress has been made in studying, from rockets and orbiting vehicles, the true solar spectrum, the reactions produced in the atmospheric gases when the sun's short wavelengths are absorbed, and the physical processes in the solar atmosphere giving rise to these radiations. Grouped together broadly as a space science, they comprise several fields, such as aeronomy, solar physics solar-terrestrial relationships, and ionospheric research. In the years to come, it is certain that orbiting observatories will monitor the ultraviolet and x-ray emissions from the sun, just as the great ground-based observatories study in visible and near-ultraviolet light the phenomena taking place in its atmosphere.

As affecting our present-day way of life, perhaps the most important action of solar short-ultraviolet and soft x-rays is in producing the several ionospheric layers; acting as mirrors, they reflect radio waves and so make possible radio communication over great distances. Far more important for mankind, however, is the solar radiation in the Schumann region, 2000 to 1300 Å. It is upon this radiation that the human race relies for survival; absorption of these wavelengths by molecular oxygen in the high atmosphere gives rise to atomic oxygen, which then reacts with molecular oxygen to form ozone. It is this permanent layer of ozone which protects all forms of terrestrial life from the lethal effects of the sun's middle-ultraviolet radiation.

V

VACUUM TECHNIQUES

The term "vacuum," which strictly implies the unrealizable ideal of a space entirely devoid of matter, is used in a relative sense in vacuum technique to denote gas pressures below the normal atmospheric pressure of 760 torr (1 torr = 1 mm of mercury). The degree or quality of the vacuum attained is indicated by the total pressure of the residual gases in the vessel which is pumped. Table I shows the accepted terminology in denoting degrees of vacuum together with the pressure range concerned, the calculated molecular density (from the equation $p = nkT$ where p is the pressure, n is the molecular density, i.e., number of molecules per cubic centimeter, k is Boltzmann's constant, and T is the absolute temperature taken to be 293 K or 20 °C) and the mean free path λ from the approximate equation for air: $\lambda = 5/p$ cm, where p is the pressure in millitorr.

Vacuum Pumps. There are several types of vacuum pumps. The two most widely used are the mechanical rotary oil-sealed pump and the vapor pump. The former provides a medium vacuum and works relative to the atmosphere; the vapor pump, on the other hand, provides a high or very high vacuum and operates relative to a medium vacuum provided by a rotary pump, referred to as a backing pump in this connection. Thus, the most widely used high-vacuum system able to establish an ultimate pressure of about 10^{-6} torr or below consists of a vapor pump backed by a rotary pump.

Four or five patterns of rotary oil-sealed pump exist, but they have in common the fact that the volume between a rotor (or rotating plunger) and a stator is divided into two crescent-shaped sections which are isolated from one another as

regards the passage of gas. Further, they are furnished with an intake port and a discharge outlet valve to the atmosphere. On revolution of the rotor (speeds of 450 to 700 rpm are used) gas is swept from the intake port, compressed, and discharged to the atmosphere via the one-way outlet valve. The mechanism is immersed in a low-vapor-pressure oil for sealing and lubrication in a small pump; larger units have a separate oil reservoir and feed device. A spring-loaded vane type of rotary oil-sealed pump is shown in Fig. 1(a). A single-stage pump of this kind provides an ultimate pressure of about 10^{-2} torr; a two-stage one with two units in cascade will give an ultimate of about 10^{-4} torr. Rotary pumps with speeds from 20 to 20 000 liters/min are commercially available, the smallest being driven by an $\frac{1}{4}$ -hp motor, the largest requiring a 40-hp motor.

These pumps handle permanent gases efficiently. Condensable vapors, e.g., water vapor, are not satisfactorily pumped because they may liquefy during the compression part of the rotation. To prevent this, gas ballast is a common provision whereby air from the atmosphere is admitted to the pump through a simple, adjustable screw valve to the region between the rotor and stator just before the discharge outlet valve. The amount of extra air admitted is readily adjusted to provide a compressed gas-vapor mixture which opens the discharge valve before vapor condensation occurs. Gas ballasting will clearly increase significantly the ultimate pressure provided by the pump, but this is not important since the gas-ballast valve can be closed after initial pumping has removed most of the water vapor.

Vapor pumps are of two main types: vapor diffusion pumps and vapor ejector pumps. Both

TABLE I. DEGREES OF VACUUM AND PRESSURE RANGES

Degree or Quality of Vacuum	Pressure Range (torr)	Molecular Density, n (molecules/cm ³)	Mean free path, λ (cm)
Coarse or rough vacuum	760--1	2.69×10^{19} — 3.5×10^{16}	6.6×10^{-6} — 5×10^{-3}
Medium vacuum	1— 10^{-3}	3.5×10^{16} — 3.5×10^{13}	5×10^{-3} —5
High vacuum	10^{-3} — 10^{-7}	3.5×10^{13} — 3.5×10^9	5— 5×10^4
Very high vacuum	10^{-7} — 10^{-9}	3.5×10^9 — 3.5×10^7	5×10^4 — 5×10^6
Ultrahigh vacuum	$< 10^{-9}$	$< 3.5 \times 10^7$	$> 5 \times 10^6$

FIG. 1. (a) A spring-loaded vane type of rotary oil-sealed pump. (b) A two-stage oil diffusion pump. (c) A diffusion pump-rotary backing pump vacuum system.

employ vapor (of either mercury or a low-vapor-pressure oil) issuing from a jet as a means of driving gas in the direction from the intake port to the discharge outlet which is maintained at a medium vacuum by a backing rotary pump. In the diffusion pump [a two-stage design utilizing oil as the pump fluid is shown in Fig. 1(b)] the vapor issuing from the top, first-stage jet is directed downward towards the backing region. Gas molecules from the intake port diffuse into the streaming vapor. The directed oil molecules collide with the gas molecules to give them velocity components toward the backing region. A large pressure gradient is thereby established in the pump so that the intake pressure may be over 100 000 times less than the backing pressure. The intake pressure may therefore be 10^{-6} torr or lower with a backing pressure of 10^{-1} torr.

In the diffusion pump, the vapor stream is not essentially influenced by the gas pumped. In the vapor ejector pump, however, the vapor stream is enabled by a higher boiler pressure to be denser and of greater speed with a higher intake pressure, so that the gas is entrained by the high-speed vapor. Viscous drag and turbulent mixing now carry the gas at initially supersonic speeds down a pump housing of diminishing cross section. The ejector pump is designed to operate with a maximum pumping speed at an intake pressure of 10^{-1} to 10^{-3} torr and with a backing pressure of 0.5 to 1 torr or more. The diffusion pump, on the other hand, is designed to have a fairly constant speed from 10^{-3} torr down to an ultimate 10^{-9} torr or much lower in a modern, bakeable stainless steel system.

An important mechanical pump which operates in the same pressure region as the oil ejector is the Roots pump, capable of very great speeds and requiring backing by a rotary oil-sealed pump.

A vacuum system consisting of a diffusion pump and a backing pump, together with baffles, cold traps and isolation valves, is shown in Fig. 1(c). The cold trap is essential if a mercury vapor diffusion pump is used and is best filled with liquid nitrogen (-196°C); otherwise, the system will be exposed to the mercury vapor pressure, which is 10^{-3} torr at 18°C .

Ultrahigh-vacuum systems with stainless steel traps and metal sealing gaskets, and bakeable

(except for the pumps) for several hours to 450°C , may be constructed on the lines of that shown in Fig. 1(c) to provide an ultimate pressure of 10^{-9} to 10^{-10} torr.

Other vacuum pumps include the sorption type based on the high gas take-up of charcoal or molecular sieve material at liquid nitrogen temperatures. Sorption pumps may be used in place of rotary pumps, with a desirable freedom from rotary pump oil vapor, especially in systems where the amount of gas to be handled is limited.

The chief rival to the vapor diffusion pump at present is the getter-ion pump of the Penning discharge type, sometimes called the sputter-ion pump, with electrodes of titanium metal. The principle of operation is illustrated by Fig. 2 where an egg-box type anode is situated between plane cathodes. The anode-cathode operating potential difference is of the order of 2 to 10 kV, and the magnetic flux density is about 3000 gauss. The chief pumping action with active gases such as hydrogen, nitrogen and oxygen is to the anode which receives deposited titanium (which has very high gas affinity) sputtered from the cathodes under the action of the positive ion bombardment. Some gas, especially the inert gases like argon, is pumped to the cathodes.

A typical multicell pump of moderate size of this type has a pumping speed of about 250 liters/sec. Much larger pumps with speeds of up to 5000 liters/sec are commercially available, as are small single-cell units with speeds of some 2 liters/sec.

The sputter-ion pumps provide a vapor-free system giving a so-called dry vacuum, and they are often incorporated in plant with molecular sieve sorption as the backing pump. For medium-size laboratory plant able to provide ultrahigh vacuum they are most attractive. Probably their chief disadvantage is that the life of the pump is only about 40 hours at 10^{-3} torr, but this increases inversely with the pressure, so that it is 40 000 hours at 10^{-6} torr. At present, they are therefore strong rivals to the diffusion pump for plant where moderate amounts of gas are handled in the lower pressure ranges.

Getter-ion pumps of the type where the titanium metal is evaporated are also used, but the current

FIG. 2. A sputter-ion pump.

tendency is for the smaller sizes in glass to be popular, while the larger metal types are replaced by the sputter-ion variety.

Cryogenic pumping is presently receiving much attention. Here basically the provision is, within an initially evacuated system, of a surface which is at such a low temperature that gas impinging on it is condensed. For example, if the surface is maintained at the temperature of liquid helium (-269°C), all other gases have insignificantly low vapor pressures at this temperature and molecules of these gases impinging on the surface would remain there. A pumping speed for nitrogen of nearly $12 \text{ liters sec}^{-1} \text{ cm}^{-2}$ of cooled surface is hence theoretically possible. Liquid nitrogen, together with molecular sieve and other sorbent surfaces, and also liquid-hydrogen (-253°C , at which the vapor pressure of solid nitrogen is 10^{-10} torr) and liquid-helium cooled metallic surfaces are being actively investigated with the possibility of providing very high pumping speeds (10^6 liters/sec is not out of question) in space simulators and other plant.

Vacuum Gauges. A considerable problem in vacuum technique is that there is only one straightforward gauge able to measure low gas pressures absolutely in the sense that its calibration is independent of the nature of the gas and can be directly referred to millimeters of mercury: the McLeod gauge (Fig. 3).

The McLeod gauge is a compression device, i.e., the gas is compressed from an initial bulb of volume V into a small diameter capillary tube of volume v per unit length so that it occupies a length h of this capillary. With the setting indicated in Fig. 3, the pressure p is given by the equation

$$p = \frac{v}{V} h^2$$

where p is in torr if h is in millimeters and with v and V in the same units.

This gauge is clumsy, contains mercury and does not record correctly the partial pressure due to any condensable vapors present. Indeed, it is best to avoid it on most vacuum systems, but it is a virtually indispensable reference gauge for calibration work.

There are several alternatives, but none of them are absolute gauges and their calibrations all depend on the nature of the gas. Of the many possibilities, the thermal conductivity gauges of the Pirani and thermocouple types are useful within the pressure range from 10^{-4} to 10 torr, and operate by virtue of the dependence of the thermal conductivity of a gas on the pressure at low pressures. Two types of ionization gauge are valuable below 10^{-3} torr. The first of these is the Penning cold-cathode gauge with a range from 5×10^{-3} to 10^{-7} torr which has been extended in the inverted magnetron type (Redhead gauge) to 10^{-11} torr or below. The second is the hot-cathode ionization gauge of which the most widely used pattern is the Bayard-Alpert gauge (Fig. 4) which has become almost indispensable as a measuring

FIG. 3. The McLeod gauge.

FIG. 4. The Bayard-Alpert hot-cathode ionization gauge.

instrument on ultrahigh-vacuum systems and has a range from 10^{-3} to 5×10^{-11} torr.

Within the hot-cathode ionization gauge, positive ions are created by impact with the residual gas molecules of the thermally emitted electrons in their paths to the positive grid (at about +150 volts w.r.t. the thermionic filament). These positive ions are attracted to the negative ion collector (at -25 to -50 volts) where the positive ion current as recorded by a calibrated dc amplifier is directly proportional to the gas pressure for a given gas and electron current. In order to minimize electron emission from the collector (indistinguishable from the arrival of positive ions) brought about by its irradiation with x-rays produced on

arrival of electrons at the positive grid, this collector is made of a thin central wire of insignificant interception of x-rays in the Bayard-Alpert gauge.

Such a gauge will typically have a sensitivity for nitrogen of about $20 \mu\text{A}$ per mA per millitorr, i.e., the positive ion current will be $20 \mu\text{A}$ with an electron current of 1 mA at a nitrogen pressure of 10^{-3} torr and it will decrease in direct proportion to the pressure.

These ionization gauges of both the hot- and cold-cathode varieties have a pumping action due to removal of positive ions to the collector and to the glass walls. This pumping action has been utilized in small glass systems to create an ultra-high vacuum. Initially, a pressure of 10^{-7} torr or below is established by a diffusion pump in the thoroughly baked ionization gauge. The gauge is then isolated from the pumps by a bakeable metal or greaseless glass valve. Subsequent operation of the gauge then reduces the pressure to the order of 10^{-10} torr. This technique, introduced by Alpert in 1950, has now been replaced by plant employing mercury or oil diffusion pumps with bakeable cold traps and metal gasket sealing, by the use of sputter-ion pumps and by cryopumping.

In the measurement of gas pressure, the determination of the partial pressures of the constituent gases is often as important as a knowledge of the total pressure. Gas analyzers for this purpose are based on the mass spectrometer of the magnetic deflection type, on the radio-frequency mass spectrometer, and on the omegatron. These gas analyzers also play an important part in leak detection techniques.

The applications of vacuum techniques are numerous and include the vacuum coating of substrates with metallic and insulating films in the production of optical mirrors, electrical resistors and capacitors, microminiature solid-state circuits, antireflection and enhanced reflection coatings on glass, conducting glass, interference filters, sorption and chemically reactive layers, etc. Further important fields of activity are the electron tube industry, vacuum drying and freeze drying, vacuum impregnation, distillation and molecular distillation, vacuum metallurgy including metal degassing and space simulation.

VAPOR PRESSURE AND EVAPORATION

Vapor Pressure. Vapor pressure is the term applied to the driving force behind the apparently universal tendency for liquids and solids to disperse into the gaseous phase. All known liquids and solids possess this fundamental property, although in some cases it is too minute to be measurable. A typical liquid will exert a vapor pressure which is constant and reproducible. This pressure is dependent only upon the temperature of the system, and increases with increasing temperatures.

The molecular theory explains the phenomenon of vapor pressure through molecular activity. The molecules of a liquid are in rapid motion, even though they are in contact with each other. This motion or activity increases with temperature. At the vapor-liquid interface, this motion results in diffusion of some molecules from the liquid into the vapor. The attraction between molecules is strong, and some of the molecules dispersed into the vapor return to the liquid. The net number of molecules escaping produces the vapor pressure. For all practical purposes, this vapor pressure can be assumed constant whether the system is at equilibrium or not, due to the extremely high rate of molecular diffusion at the interface of the two phases.

In solids, the attractive forces of the molecules are so dominant that each is more or less frozen in place. Some diffusion does occur, however, as evidenced by the evaporation of ice, the odor of moth balls, and the slow diffusion or alloy formation of some metals kept in intimate contact. This vapor pressure increases with temperature, but is also a function of the molecular arrangement of the solid. As some solids such as sulfur are heated and molecular rearrangements take place, forming another allotrope of the same element, the vapor pressure changes sharply as this rearrangement occurs.

Vapor pressure can only be exhibited when the molecular activity is at a low enough level to permit continuous contact of the molecules and thus formation of a liquid. The maximum temperature at which this is possible is a fundamental property and is called the *critical temperature*. Above this temperature the material cannot be compressed to form a liquid, and only one phase results. This temperature is 705.4°F for water and -399.8°F for hydrogen.

The fundamental relationship between temperature and vapor pressure can be derived from thermodynamic laws. With certain limiting assumptions, the Clausius-Clapeyron equation is most often applied:

$$\frac{dp}{dT} = \frac{qp}{RT^2}$$

where q is the heat of vaporization. Because of these limiting assumptions, the integrated form of this equation is used in practice primarily as a guide to develop methods of correlating and plotting vapor pressure data.

The vapor pressure of a solution containing a nonvolatile substance (e.g., salt in water) is lower than that of the pure liquid. This phenomenon can again be explained by interference with the liquid molecular activity by the dissolved substances. The relationship between this vapor pressure depression and the concentration of the dissolved substance is valid for most substances at low concentrations. It was found to be dependent on the relative numbers of molecules of the solute and the solvent, and allowed accurate determinations of molecular weights of unknown solutes. If the Clausius-Clapeyron equation given above is combined with the above concentration relationship, it can be shown that:

$$\Delta T = \frac{RT^2}{q} \cdot C$$

where ΔT is the elevation of the boiling point, and C is the ratio of solute to solvent. This defines the effect of any solute on the vapor pressure exhibited by any solvent of latent heat q .

In the same manner, the vapor pressure of one component of a solution of two liquids has a different relationship with temperature than if it were pure. For many liquid mixtures, such as most hydrocarbon mixtures, the vapor pressure of the components vary directly from that exhibited in the pure form as their molar concentration in the solution. This relationship is known as Raoult's law:

$$\text{Partial pressure} = P_0 x$$

where x is the molar concentration of the component in the liquid and P_0 is the vapor pressure of the pure component at the same temperature as the mixture. A mixture following this rule is called an *ideal* solution, and its total volume is the sum of its components' volume.

If the gas phase above the liquid is also "ideal," the partial pressure of a component in this phase is equal to the total system pressure times the mole fraction of the component in the gas phase. This is called Dalton's law:

$$\text{Partial pressure} = P_t y$$

Combining these two formulas, it can be seen that:

$$\frac{y}{x} = \frac{P_0}{P_t} = K$$

for any particular temperature. This relationship can largely define many very complex liquid mixtures if the pressures used in the correlation are corrected by experimental data for deviation from the ideal.

A different relationship results if two liquids are relatively immiscible in each other. Molecular interference is minimal, and the total pressure exerted is equal to the sum of that of the individual pure components. The fundamental property of vapor pressure is thus dependent on temperature and composition of the material considered. These known and reproducible relationships have great technical application.

Vapor pressure relations can be used to determine heats of solution, heats of sublimation, and heats of fusion. Problems dealing with the solution of gases in liquids and adsorption of gases by solids are best handled by vapor pressure concepts. In dealing with solutions of miscible liquids, the most simple and useful relationship involves plotting the mole fraction y of one component in the vapor against x , the mole fraction of the component in the liquid. The ratio of $\frac{y}{x}$ is called

the phase equilibrium constant K and is used for definition of bubble points and dew points of simple and complex hydrocarbon mixtures over temperature and pressure ranges to near the critical.

Evaporation. The above effects of mixtures and of solutes on vapor pressure of a component are the very reasons why continuous generation of vapor (or *evaporation*) is the major tool of most process separations.

These effects permit us to separate salts from solutions, to separate liquid components from mixtures, and to use the energy relationships in process control of all kinds.

When molecules of a liquid do leave the surface and become vapor, they do so by overcoming the rather large attractive forces existing when they were in the liquid state. These forces were large since the molecules were in very close proximity in the liquid. Overcoming these attractive forces requires *energy*, heat energy, this is named the "*latent heat*" or "heat of vaporization" of the fluid. In general, this is in terms of heat units per unit of material, such as Btu per pound. In magnitude, latent heat will decrease as the liquid temperature increases or as the kinetic energy of the molecules increases. At the critical temperature, there is no latent heat—the molecules are in such an excited state that formation of a liquid is not possible.

For continuous evaporation, a continuous supply of energy is required. An available utility such as steam is a typical source.

Depending on the process, the evaporation is done:

(1) In equipment named "evaporators" such as the popular LTV of forced or natural circulation design used in acid concentration, salt production, sugar solution concentration and others.

(2) In processing distillation towers in a stepwise manner, tray to tray, resulting in a slight change in composition at each tray until required terminal conditions of overhead and bottom composition are reached.

(3) In reactors of various designs where one or more components are driven off frequently by the heat of reaction.

(4) In "cooling towers" where the desired effect is not the separation or concentration of components but the use of the latent heat of evaporating water to remove unwanted process heat.

(5) In all steam generating boilers.

(6) In any process step where a liquid/vapor phase change occurs.

The concentration and energy relationships discussed before apply.

Evaporation is thus the most widely used tool of nature and of industry. For this reason, an intimate knowledge of the theory of heat transfer and of the large quantity of empirical data available is essential to understand and develop almost any industrial process.

VECTOR PHYSICS

The Emergence of Vectors in Physics. A physical variable whose values can be specified by single numbers is called a *scalar concept*. The number 212 on the Fahrenheit thermometer specifies the boiling temperature of water at standard pressure. Temperature then is a scalar concept. By contrast, even when a suitable reference frame has been selected, the instantaneous velocity of a rocket is not fully described by stating that its speed is 2000 mph. If one also designates the *direction of the motion* (say by stating that it heads northeast and climbs at elevation 60°), then the velocity is unambiguously described. Velocity is an example of a *vector concept*.

Some of the special properties of vector concepts have been recognized for hundreds of years, e.g., the ancient fact that forces combine according to the familiar parallelogram law (see article on STATICS). Mathematical tools for dealing with directed quantities in three dimensions are outstanding products of nineteenth century mathematics. It now seems entirely natural to express key propositions of classical physics using vector algebra and vector calculus. A few decades ago, however, this was a controversial subject. Between 1891 and 1894, Peter G. Tait, Oliver Heaviside, Josiah Willard Gibbs, and others published fiery articles (still exciting reading) in the British journal *Nature*. Tait was a devoted promoter of quaternions, developed by his mentor, William Rowan Hamilton, as the proper tool for spatial physics. Gibbs, familiar with the work of Hamilton and also the more general theories of H. Grassmann, had devised his own treatment of physical problems. Heaviside was an indomitable advocate of the views of Gibbs. All of these men left their imprint on mathematics and physics. The notation of Gibbs, which mainly is followed here, has been particularly influential in the contemporary applications of vector mathematics.

Vector Algebra. To the question, "What is a vector?" one may give several reasonably respectable elementary answers. A vector is an arrow of a particular length and direction. A vector is a class of equivalent arrows. A vector is an ordered pair of points. A vector is a class of equivalent ordered pairs of points. A vector is an ordered triple of numbers. A vector is an ordered sequence of n numbers (which is called a scalar if $n = 1$!).

A vector is one of the undefined elements of a vector space. Each answer makes sense in its own context. The last answer provides a pattern which includes the others and offers the quickest approach to the algebra of vectors.

A *vector space* is an algebraic structure whose elements are called vectors (usually denoted here by boldface type: **A**, **B**, **C**, etc.), whose two operations are called *addition* and *multiplication by numbers* (we use real numbers throughout), and for which certain postulates are satisfied. These postulates should be regarded as a catalog of fundamental properties of such a structure. Other properties may be derived from them. The postulates may be stated as follows:

(1) For every pair of vectors **A**, **B** there is a vector sum such that

$$\mathbf{A} + \mathbf{B} = \mathbf{B} + \mathbf{A}$$

(2) For every triple of vectors, **A**, **B**, **C**, we have the equality

$$(\mathbf{A} + \mathbf{B}) + \mathbf{C} = \mathbf{A} + (\mathbf{B} + \mathbf{C})$$

(3) There is a null vector **O**, such that for every vector **A**,

$$\mathbf{A} + \mathbf{O} = \mathbf{A}$$

(4) Every vector **A** has an opposite vector $-\mathbf{A}$, such that

$$\mathbf{A} + (-\mathbf{A}) = \mathbf{O}$$

(5) For every number c and every vector **A** there is a vector $c\mathbf{A}$ such that

$$c\mathbf{A} = \mathbf{A}c$$

(6) For every pair of numbers c , c' and every vector **A**,

$$(c + c')\mathbf{A} = c\mathbf{A} + c'\mathbf{A}, \quad c(c'\mathbf{A}) = (cc')\mathbf{A}$$

(7) For every pair of vectors **A**, **B** and every number c ,

$$c(\mathbf{A} + \mathbf{B}) = c\mathbf{A} + c\mathbf{B}$$

(8) The particular product $1\mathbf{A}$ is equal to **A**.

The geometric and physical significance of this list of algebraic properties is more clear when one considers suitable definitions of the two operations for particular vector spaces. For example, if the vectors represent forces, and hence are drawn as arrows, addition is composition of forces by the parallelogram rule, while multiplication by a number is merely an alteration of the magnitude (denoted by vertical bars) of the force according to the rule: $|c\mathbf{F}| = |c||\mathbf{F}|$. Multiplication by a negative number reverses direction. As a second example, if the vectors are triples of numbers (as in statics when components are listed), the two operations are at once defined thus:

$$(a_1, a_2, a_3) + (b_1, b_2, b_3)$$

$$= (a_1 + b_1, a_2 + b_2, a_3 + b_3)$$

$$c(a_1, a_2, a_3) = (ca_1, ca_2, ca_3)$$

One can easily verify that triples satisfy all eight postulates.

Two additional operations are of particular importance in physics. First, an *inner product* associates with each pair of vectors \mathbf{A}, \mathbf{B} a number, designated by $\mathbf{A} \cdot \mathbf{B}$, such that for all vectors $\mathbf{A}, \mathbf{B}, \mathbf{C}$ and every number c , the following identities hold:

$$(9) \mathbf{A} \cdot \mathbf{B} = \mathbf{B} \cdot \mathbf{A}$$

$$(10) \mathbf{A} \cdot (\mathbf{B} + \mathbf{C}) = \mathbf{A} \cdot \mathbf{B} + \mathbf{A} \cdot \mathbf{C}$$

$$(11) c(\mathbf{A} \cdot \mathbf{B}) = (c\mathbf{A}) \cdot \mathbf{B}$$

A final postulate for a vector space with inner product (called a *euclidean vector space*) is

$$(12) \mathbf{A} \cdot \mathbf{A} = 0 \text{ if and only if } \mathbf{A} = \mathbf{O}, \text{ and}$$

$$\mathbf{A} \cdot \mathbf{A} > 0 \text{ if and only if } \mathbf{A} \neq \mathbf{O}.$$

The physical concept of work provides a strong motivation for the usual definition of inner product. A force \mathbf{F} and a displacement \mathbf{S} are assigned a work $|\mathbf{F}||\mathbf{S}|\cos(\mathbf{F}, \mathbf{S})$ where (\mathbf{F}, \mathbf{S}) is the angle between vectors parallel to \mathbf{F} and \mathbf{S} . The defining formula for inner products of arrows is taken to be

$$\mathbf{A} \cdot \mathbf{B} = |\mathbf{A}||\mathbf{B}|\cos(\mathbf{A}, \mathbf{B})$$

Similarly, for triples

$$(a_1, a_2, a_3) \cdot (b_1, b_2, b_3) = a_1b_1 + a_2b_2 + a_3b_3$$

To prove that these two definitions satisfy postulates (9) through (12) is by no means trivial.

Similarly, an *outer product* associates with each ordered pair of vectors \mathbf{A}, \mathbf{B} a vector designated by $\mathbf{A} \times \mathbf{B}$, and possesses the following key properties. For all vectors $\mathbf{A}, \mathbf{B}, \mathbf{C}$ and every number c ,

$$(13) \mathbf{A} \times \mathbf{B} = -\mathbf{B} \times \mathbf{A}$$

$$(14) \mathbf{A} \times (\mathbf{B} + \mathbf{C}) = \mathbf{A} \times \mathbf{B} + \mathbf{A} \times \mathbf{C}$$

$$(15) (c\mathbf{A}) \times \mathbf{B} = c(\mathbf{A} \times \mathbf{B})$$

$$(16) \mathbf{A} \times (\mathbf{B} \times \mathbf{C}) = (\mathbf{A} \cdot \mathbf{C})\mathbf{B} - (\mathbf{A} \cdot \mathbf{B})\mathbf{C}$$

The physical concept of moment of a force about a point leads naturally to a definition of outer product for arrows. Let \mathbf{F} be a vector representing a force acting at a point Q and for some point P let \mathbf{R} denote the arrow PQ . The moment \mathbf{M} of the force about the point P has magnitude given as follows:

$$|\mathbf{M}| = |\mathbf{R} \times \mathbf{F}| = |\mathbf{R}||\mathbf{F}|\sin(\mathbf{R}, \mathbf{F})$$

If $\sin(\mathbf{R}, \mathbf{F}) \neq 0$, the direction of \mathbf{M} is perpendicular to the plane of the point P and the arrow \mathbf{F} . We then write

$$\mathbf{M} = \mathbf{R} \times \mathbf{F} = [|\mathbf{R}||\mathbf{F}|\sin(\mathbf{R}, \mathbf{F})]\mathbf{N}$$

where \mathbf{N} is a vector of magnitude 1 (a *unit vector*) perpendicular to the PF plane. The sense of \mathbf{N} is usually taken so that the rotation of \mathbf{R} into the direction of \mathbf{F} determines \mathbf{N} by the right-hand rule. And for triples:

$$(a_1, a_2, a_3) \times (b_1, b_2, b_3)$$

$$= (a_2b_3 - a_3b_2, a_3b_1 - a_1b_3, a_1b_2 - a_2b_1)$$

For either of these models (arrows or triples), property (16) is quite remarkable. By applying it in two different ways to $\mathbf{A} \times [\mathbf{A} \times (\mathbf{A} \times \mathbf{B})]$, the reader may show, with the aid of property

(13), that $\mathbf{A} \cdot \mathbf{A} \times \mathbf{B}$ vanishes for all vectors \mathbf{A}, \mathbf{B} . Property (16) also leads easily to the Jacobi identity:

$$\mathbf{A} \times (\mathbf{B} \times \mathbf{C}) + \mathbf{B} \times (\mathbf{C} \times \mathbf{A}) + \mathbf{C} \times (\mathbf{A} \times \mathbf{B}) = \mathbf{O}$$

For the purposes of simple physical or geometric applications, the transition from arrows to triples is immediate. For a given reference frame, one lets (a_1, a_2, a_3) denote the three components (parallel to axes) of the arrow \mathbf{A} . These components may be computed by use of the inner product formula. Let $\mathbf{i}_1, \mathbf{i}_2, \mathbf{i}_3$ be unit vectors parallel to three mutually perpendicular positive coordinate axes. Then, relative to these chosen axes, an arrow \mathbf{A} has components as follows:

$$a_1 = \mathbf{A} \cdot \mathbf{i}_1, a_2 = \mathbf{A} \cdot \mathbf{i}_2, a_3 = \mathbf{A} \cdot \mathbf{i}_3$$

Note that for each subscript j , since $|\mathbf{i}_j| = 1$, we have

$$a_j = |\mathbf{A}|\cos(\mathbf{A}, \mathbf{i}_j)$$

The preceding formula is used in statics for computing components of a force. One may think of each arrow \mathbf{A} as represented by the triple (a_1, a_2, a_3) of its components. In fact, one can make the merger complete by resolving each arrow into a sum of arrows parallel to the chosen axes:

$$\mathbf{A} = a_1\mathbf{i}_1 + a_2\mathbf{i}_2 + a_3\mathbf{i}_3$$

In this article, arrows and triples appear as alternate but related representations of physical concepts. For details on the ideas of this section see reference 2.

Vector Concepts in Elementary Geometry and Kinematics. In particle kinematics the most primitive ideas are position and displacement. Relative to an origin O the arrow OP is called the *position vector* of a particle at the point P . The displacement from P to P' is described by the arrow $\mathbf{D} = PP'$. One can easily see that $OP + PP' = OP'$, or $\mathbf{R} + \mathbf{D} = \mathbf{R}'$. It is natural now to introduce the notation of vector subtraction:

$$\mathbf{R}' = \mathbf{R} + \mathbf{R}' - \mathbf{R} = (-\mathbf{R}) + \mathbf{R}'$$

Hence, in vector geometry, a *displacement is equal to a difference of position vectors*. For a time interval Δt we often write the displacement as $\Delta \mathbf{R}$.

From the definitions of arrow operations, a number of geometric conclusions may be drawn:

(1) Non-null vectors \mathbf{A}, \mathbf{B} are *parallel* (or *anti-parallel*) if and only if $\mathbf{A} \times \mathbf{B} = \mathbf{O}$.

(2) Non-null vectors \mathbf{A}, \mathbf{B} are *perpendicular* if and only if $\mathbf{A} \cdot \mathbf{B} = 0$.

(3) An *equation for a plane* through a fixed point P' with position vector \mathbf{R}' and normal to a fixed vector \mathbf{N} is given by $(\mathbf{R} - \mathbf{R}') \cdot \mathbf{N} = 0$. This means for any point $P \neq P'$ on the plane, the arrow PP' is perpendicular to \mathbf{N} .

(4) Similarly, an *equation for a line* through P' parallel to \mathbf{N} is given by $(\mathbf{R} - \mathbf{R}') \times \mathbf{N} = \mathbf{O}$.

For further applications of vectors to elementary geometry, see Appendix 2 of reference 2.

Note that if one treats the position vector of P as a triple (x_1, x_2, x_3) , using coordinates, instead of as an arrow, the results just described are still valid.

If we define *velocity* as displacement per time, then we may represent the vector V as a derivative:

$$V = \lim_{\Delta t \rightarrow 0} (\Delta R / \Delta t) = dR/dt$$

Similarly, acceleration A is defined by $A = dV/dt$. Here again, when a reference frame has been chosen, one may employ triples:

$$V = (dx_1/dt, dx_2/dt, dx_3/dt)$$

$$A = (d^2x_1/dt^2, d^2x_2/dt^2, d^2x_3/dt^2)$$

In numerous physical applications, the use of vectors for geometric descriptions is effective. Consider a gas escaping through a surface element of area Δa . Call the outward unit vector normal to the surface element N . The area element may be treated as a vector

$$\Delta A = (\Delta a)N$$

If the velocity of escape is uniformly V , the outward flux (in particles per second) is given by

$$\Delta(\text{flux}) = \rho V \cdot \Delta A$$

where ρ is the number of particles per unit volume. Formulas for efflux under more general conditions may be found in books on kinetic theory, or in reference 2.

For a rigid body spinning about a fixed axis, the angular velocity is a vector ω directed along the axis of rotation according to the right-hand rule. Its time derivative is the angular acceleration α . If we take the origin of position vectors on the axis, the induced velocity and acceleration for a point of position vector R are given by

$$V = \omega \times R$$

$$A = \alpha \times R + \omega \times (\omega \times R)$$

The second term in the acceleration formula is called *centripetal acceleration*. Note that when $\alpha = 0$, $A = \omega \times V$ (see article on ROTATION — CIRCULAR MOTION). The preceding formula for centripetal acceleration in uniform circular motion has an interesting rotational analogue:

$$\alpha = \omega_p \times \omega_s$$

The subscripts stand, respectively, for precession and spin. This new formula describes uniform precession for gyroscopic motion (See article on GYROSCOPE).

Vector Concepts in Dynamics. Newton's second law (see article on DYNAMICS) may be summarized in vector equations:

$$F_1 + F_2 + \dots + F_n = (d/dt)(mV) = mA$$

The addition in the left member is vector addition. The product in the right member is multiplication

of a vector by a number. The left member may be written as

$$\sum_1^n F_i = \bar{F}$$

where \bar{F} denotes a resultant force. The abbreviated equation of motion

$$\bar{F} = m\bar{A}$$

where \bar{F} and \bar{A} stand for arrows, provides an expressive condensation of a basic physical proposition. The same equation serves as the key to analytical procedures if triples are used instead of arrows:

$$(\bar{f}_1, \bar{f}_2, \bar{f}_3) = m(d^2x_1/dt^2, d^2x_2/dt^2, d^2x_3/dt^2)$$

This vector equation yields three component equations:

$$\bar{f}_i = m d^2x_i/dt^2, \quad i = 1, 2, 3$$

In vector physics, the arrow representation of vector concepts repeatedly provides an easily visualized theoretical development, while the triple representation, for well-chosen axes, provides the strongest approach to computation. Some mechanical concepts are next listed in both forms.

Momentum of a particle:

$$mV = m(dx_1/dt, dx_2/dt, dx_3/dt)$$

Impulse exerted by a force:

$$\int_{t_0}^{t_1} F dt = \left(\int_{t_0}^{t_1} f_1 dt, \int_{t_0}^{t_1} f_2 dt, \int_{t_0}^{t_1} f_3 dt \right)$$

Work done by a force:

$$\int_R F \cdot dR = \int_{x_1}^{x_1'} f_1 dx_1 + \int_{x_2}^{x_2'} f_2 dx_2 + \int_{x_3}^{x_3'} f_3 dx_3$$

The integrands of the preceding equation must, of course, assume the values dictated by the path along which the force is allowed to act. For rotation about an axis, angular momentum is given by $I\omega$, I being the moment of inertia. In more general situations, the equivalent notion of moment of momentum is appropriate: $H = \int R \times V dm$. The details are not discussed here,

but, corresponding to $\sum F = \frac{d}{dt}(mV)$ we may write equations of the form

$$\sum R \times F = \frac{d}{dt} H$$

In rotation about a fixed axis, the second equation takes the familiar form

$$\sum M = \frac{d}{dt}(I\omega) = I\alpha$$

where each M is a moment about the axis, interpreted as a vector along it.

Vector Fields and Their Uses. A scalar field (scalar point function) assigns to each point (and

hence to each position vector) in a suitable domain a particular number. For example, to each point, \mathbf{R} , in a room is assigned a number called temperature, $\theta(\mathbf{R})$, another number called density, $\rho(\mathbf{R})$, another number called height above sea level, $h(\mathbf{R})$. Similarly, to each point in a room may be assigned a vector called gravitational field intensity, $\mathbf{G}(\mathbf{R})$, another vector called velocity (e.g., of air currents), $\mathbf{V}(\mathbf{R})$, another vector called magnetic flux density, $\mathbf{B}(\mathbf{R})$. These exemplify vector fields. When such scalar or vector fields have derivatives, important new fields may be derived. The pressure function in an ideal fluid is a scalar field $p(\mathbf{R})$. A related vector field is the pressure gradient, $\text{grad } p(\mathbf{R})$. The *pressure gradient* is a function assigning to each point the direction and magnitude of the maximum directional derivative of p . This new vector function is often written ∇p . Pressure gradient is intimately related to buoyant force: the net buoyant force per volume at \mathbf{R} equals $-\nabla p(\mathbf{R})$. Thus an equation for hydrostatic equilibrium is

$$\rho(\mathbf{R})\mathbf{G}(\mathbf{R}) = -\nabla p(\mathbf{R})$$

In terms of ordinary coordinates, the vector ∇p may be represented as triple:

$$\nabla p = (\partial p / \partial x_1, \partial p / \partial x_2, \partial p / \partial x_3)$$

Many other examples of gradient fields occur in physics. For instance, if a field intensity is conservative, it equals minus the gradient of a suitable potential function.

One simple vector field assigns to each position vector \mathbf{R} the corresponding velocity vector, $\mathbf{V}(\mathbf{R})$. For a rigid body rotating about a fixed axis, taking the origin on the axis, a formula for the velocity field is

$$\mathbf{V}(\mathbf{R}) = \boldsymbol{\omega} \times \mathbf{R}$$

where $\boldsymbol{\omega}$ is the instantaneous angular velocity. For the most general motion of a rigid body the formula is almost as simple: for any fixed point \mathbf{R}' of the body,

$$\mathbf{V}(\mathbf{R}) = \mathbf{V}(\mathbf{R}') + \boldsymbol{\omega} \times (\mathbf{R} - \mathbf{R}')$$

For details see reference 2.

The velocity pattern for a fluid will usually be more complicated than the one just considered. Compressions or expansions might occur. This sort of tendency may, at each point, be evaluated by the net outward flux per volume, called the *divergence* of the velocity field, written $\text{div } \mathbf{V}(\mathbf{R})$. Since this flux is measured in terms of volume rather than number of particles (as on p. 753), $\rho(\mathbf{R})$ is 1, and we have

$$\text{div } \mathbf{V}(\mathbf{R}) = \lim_{\Delta v \rightarrow 0} \frac{1}{\Delta v} \int_{\Delta v} \mathbf{V} \cdot d\mathbf{A}$$

Δa is the area of the solid element of volume Δv for which the net efflux per volume is expressed. Each such solid element contains the point with position vector \mathbf{R} . Divergence yields a scalar

field for a given vector field. Using cartesian coordinate triples

$$\text{div}(\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3) = \partial v_1 / \partial x_1 + \partial v_2 / \partial x_2 + \partial v_3 / \partial x_3$$

Since the net efflux per volume of mass is merely the rate of decrease of density, one can write at once the *equation of continuity* of hydromechanics

$$\text{div}(\rho \mathbf{V}) = -\partial \rho / \partial t$$

The concept of divergence has particular use in the theory of electromagnetism. For free space,

$$\text{div } \mathbf{B} = 0$$

$$\text{div } \mathbf{E} = 4\pi \rho$$

where \mathbf{B} is the magnetic flux density and \mathbf{E} the electric field intensity. This time ρ stands for electric charge density.

For a rigid body, the rotational aspect of a velocity field has been characterized by the vector $\boldsymbol{\omega}$. For a more general differentiable velocity field, one considers a derived vector function proportional to the local angular velocity vector. Only a formal cartesian expression for this new field, $\text{curl } \mathbf{V}$, is given here. For more general treatments not depending on particular coordinates, see reference 7.

$$\text{Curl}(\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3) = (\partial v_3 / \partial x_2 - \partial v_2 / \partial x_3,$$

$$\partial v_1 / \partial x_3 - \partial v_3 / \partial x_1,$$

$$\partial v_2 / \partial x_1 - \partial v_1 / \partial x_2)$$

The concept of curl plays a vital role in many parts of physics. A field intensity is conservative if and only if its curl vanishes. The interrelationships between electrical and magnetic fields are most concisely expressed in terms of curl (see Maxwell's equations in most books on electromagnetism).

The formal expressions for gradient, divergence, and curl suggest regarding

$$\nabla = \mathbf{i}_1 \partial / \partial x_1 + \mathbf{i}_2 \partial / \partial x_2 + \mathbf{i}_3 \partial / \partial x_3$$

as a vector operator. Here we have used $\mathbf{i}_1, \mathbf{i}_2, \mathbf{i}_3$ as unit vectors parallel to coordinate axes, i.e., as abbreviations for the triples $(1, 0, 0)$, $(0, 1, 0)$, and $(0, 0, 1)$. With this convention we may write:

$$\text{grad } p = \nabla p$$

$$\text{div } \mathbf{V} = \nabla \cdot \mathbf{V}$$

$$\text{curl } \mathbf{V} = \nabla \times \mathbf{V}$$

For more information about formal uses of ∇ see Appendix 3 of reference 2 or 8.

Extensions of Elementary Vector Physics. In preceding sections, we considered several vector functions of position. The function $\mathbf{V}(\mathbf{R}) = \boldsymbol{\omega} \times \mathbf{R}$ is a *linear* function, and hence can be represented in matrix notation. Equations for changes of coordinates can be expressed as translations combined with linear transformations (usually orthogonal). Linear transformations also occur in

expressions for strain in the theory of elasticity. Further details on linear transformations and vector physics ^{1,2,4,6} and treatments ^{1,5,7,10} of vectors in a more advanced mathematical setting can be found in the literature.

In this article we have considered mainly three-dimensional vector spaces. For the use of four-dimensions in special relativity,⁶ for vector treatments of variational mechanics,^{3,4} and for higher dimensional vectors used in phase spaces,² see the references listed below.

VELOCITY OF LIGHT

Every elementary electric charge occupies a small volume. The charge is surrounded by a radially directed electric field, the strength of which decreases by the square of distance. By any motion with a velocity $v > 0$ of the charge relative to some fixed point, the distance and/or direction is changed and, thereby, the (vector) value of the field strength at the point. Here the field change occurs a while after the moment of charge motion. Otherwise expressed, the field change propagates with a finite velocity, usually labeled c . Moreover,

during the short time for the action from a *certain part* of the charge volume to pass the rest of it, the volume moves a small distance proportional to v/c . This very small displacement creates the magnetic field always associated with an electric field change. In fact, magnetism is due to a, usually very small, part of the electric field.

Any change in the electromagnetic field propagates with the very high velocity of $c = 3 \times 10^{10}$ cm/sec, called the velocity of light. For, if the charge motion happens to be an oscillation of frequency ν between 4×10^{14} and 8×10^{14} cps, we note the corresponding field variations as visible light. According to definition it is

$$c = \nu \cdot \lambda \quad (1)$$

where λ is the wavelength in vacuum. The movements of the elementary charges are mostly oscillatory. By means of the field, after the delay due to c , they act on surrounding charges, and in that way all events in the atomistic world depend on the value of c . Therefore, the knowledge of c has turned out to be of extreme importance to our modern civilization.

The wave velocity according to Eq. (1) has a constant value, independent of all movements and, strictly speaking, independent of the medium where the propagation takes place. In a transparent body, in the intermediate space the action among the elementary charges of the atoms disperses with the velocity c . By inertia, the oscillating of the charges due to the active field is somewhat delayed as compared to the field. Now, the oscillating charge itself is a radiating source and its own delayed field interferes with the original one, creating a sum-wave. The velocity v of which is $v < c$. Exceptionally, in cases of resonance and absorption $v > c$. Our observation of light propagation in a substantial body relates to that slower interference wave. For the body, e.g., the medium of atmospheric air, we obtain corresponding to Eq. (1):

$$v = \nu \cdot \lambda_a \quad (2)$$

From plain optical geometry we know that the refractive index of a medium is

$$n = \frac{c}{v} = \frac{\lambda}{\lambda_a} \quad (3)$$

The technique for determining the wavelengths of light has progressed very far, and one can easily obtain an accurate value of n . For visible light, n depends on the wavelength used, according to

$$n = A + \frac{B}{\lambda^2} + \frac{C}{\lambda^4} \quad (4)$$

where A , B and C are positive constants. Close to resonance, the formula is not valid.

Direct determinations of the velocity of light, usually performed in air, are all based on the measurement of the time for a light pulse to cover a known distance. Such a pulse means an increase, followed by a decrease of the amplitude of the light vibrations. What we observe is energy exchange associated with the amplitude changes,

and as a result, we obtain the propagation velocity of the light energy. A change of amplitude is, however, equivalent to an interference among a series of adjacent wavelengths, since that change is created by just such an interference. The light pulse, therefore, consists of a whole group of adjacent wavelengths, interfering with each other. Interference is a sum-product. If the participating waves have different velocities, one will find by simple addition of two sine oscillations, that the group formed has a velocity different from those of the waves creating the group. On the surface of a calm sea, we observe a group of waves moving forward. The waves are created at the back of the group, travel through it, and disappear at the front. The difference between wave and group velocity is directly proportional to the wavelength and to the dependence of the wave velocity on the wavelength. Thus, calling the group velocity u , we obtain the difference:

$$v - u = \lambda_n \cdot \frac{dv}{d\lambda_n} \quad (5)$$

Analogously to Eq. (3), we introduce a "group index"

$$n_g = \frac{c}{u} \quad (6)$$

If, as in the case of air, $dv/d\lambda_n$ is a small quantity, we get, after some recalculation,

$$n_g = n - \lambda \cdot \frac{dn}{d\lambda} \quad (7)$$

From Eq. (4) it is evident that $dn/d\lambda$ is a negative quantity, i.e., $n_g > n$. In vacuum, all velocities are equal: $u = v = c$.

The group velocity refers to the energy transport. Thus, in a medium there are the original waves of vacuum velocity c . By interference with waves from local charge oscillators, they create a wave system characteristic of the medium being considered and with the velocity $v < c$. By external energy action, that system is divided into an increasing number of adjacent waves, again interfering, of "second order," thereby forming groups of velocity $u < v$ (if normally $dn/d\lambda < 0$). Application of Eq. (7) to Eq. (4) yields:

$$n_g = A + \frac{3B}{\lambda^2} + \frac{5C}{\lambda^4} \quad (8)$$

In the case of visible light or $\lambda = 0.4 - 0.8 \mu$ ($\mu = 0.001$ mm) and in dry air of 0°C , 760 mm Hg, $A = 1.000287619$, $B = 16.204 \times 10^{-7}$, $C = 0.1391 \times 10^{-7}$ (based on values derived by Edlen). Inserting n_{0g} corresponding to the λ used, we get

$$n_g = 1 + \frac{n_{0g} - 1}{1 + \alpha t} \cdot \frac{p}{760} - 0.55 \times 10^{-7} \cdot \frac{e}{1 + \alpha t} \quad (9)$$

where t is expressed in degrees Celsius, p in millimeters Hg, e in millimeters Hg of humidity, and $\alpha = 1/273$. For visible light, the error of Eq. (9) is less than 5×10^{-8} .

For micro- and radar waves with $\lambda > 700 \mu$ the influence of λ in Eq. (8) is insignificant. Increasing influence of humidity, however, makes

$$n = 1 + \left[\frac{103.64}{T} (p - e) + \frac{86.26}{T} \left(1 + \frac{5748}{T} \right) e \right] \times 10^{-6} \quad (10)$$

where $T = t + 273.16$. By using 103.64 in place of 103.49 as recommended by the International Association of Geodesy, the influence of a CO_2 -term is partly compensated for. The uncertainty of Eq. (10) is about 5×10^{-7} .

There are a variety of methods for the determination of c . Among the direct ones, is the measurement of the travel time for a light pulse to cover a known distance. Usually there is a continuous series of pulses; i.e., the intensity is varied with a definite and known frequency. At every moment, there is a definite state of phase of the variation period. After reflection, the light returns, and one makes a phase comparison between emitted and received intensity. Thus, the intensity variation is used as a clock for the measurement of the running time. If the phase comparison is based on having the maximum of emitted light intensity coincide with the maximum of received intensity, the running time evidently is an even multiple of the period (= time) of a complete intensity variation cycle. Usually only one definite multiple number yields reasonable values, and there is no need for a special determination of the multiple.

The indirect methods are of much more varied character.

Determination of c . Galileo was the first to try to show a finite light velocity. In his direct method, he used lanterns which could be screened off rapidly. The time elapsed on a distance of few kilometers was, of course, too small to be observed visually.

In August 1676 at Paris, the Danish astronomer Ole Römer determined the revolution period of a satellite of Jupiter by its eclipse times into the planet's shadow. He used the result, 42 hours, to calculate the point of time for an eclipse occurring in November. It really occurred 10 minutes later. Römer explained this by the longer time for the light to reach the earth, now at a considerably greater distance from Jupiter. From the dimensions of the earth's orbit Römer defined c to be

$$c = 214\,300 \text{ km/sec}$$

A modern value according to the same method is $299\,840 \pm 60$ km/sec.

In 1725 the Englishman Bradley discovered astronomic aberration. Due to the velocity v of the earth in her orbit, the apparent direction to the stars normal to v is changed by v/c . Bradley could detect and measure the angle v/c because of its alternate sign for opposite parts of the earth orbit. Knowing v Bradley computed

$$c = 295\,000 \text{ km/sec}$$

A modern value is $299\,857 \pm 120$ km/sec.

In 1849 the Frenchman Fizeau took the next step. By projection of the image of a point source on the edge of a rapidly revolving cogged wheel, he got the required light pulse series. A blink or pulse passing through a cog interspace traveled the distance of 8633 meters to a reflector and back again along the optically identical path. Once more, now in the opposite direction, the pulse reached the cogged edge. For a suitable rotational speed the next cog interspace had now moved into position to let through the pulse; a case of "coincident maxs" (maxima). The time was computed from the revolution speed and the number of cogs. Fizeau's value was:

$$c = 315\,300 \pm 500 \text{ km/sec}$$

In 1850, after an idea of Arago, using a point light source, Fizeau's compatriot Foucault directed a beam of constant intensity to a rapidly revolving plane mirror. During the time for the light to cover the distance to a second fixed mirror and back, the revolving mirror had turned through a small angle, and the image of the light source was slightly displaced from its position when the mirror was stationary. Foucault's value was:

$$c = 298\,000 \pm 500 \text{ km/sec}$$

In 1856 the German scientists Kohlrausch and Weber achieved a very important indirect determination. The magnetic field strength depends on rc , the charge velocity r creating the magnetic field. Therefore, based on the same unity of force, the ratio between the unit of charge in electric and in magnetic measuring systems becomes c . Kohlrausch and Weber measured a charge (1) by its attraction to a second equal charge and (2) by the current produced at the passage of the charge through a galvanometer which showed a deflection due to the magnetic force. From (1)/(2) c , they got

$$c = 310\,800 \text{ km/sec}$$

Rosa and Dorsey in 1906 measuring a capacity obtained $299\,784 \pm 30 \text{ km/sec}$.

In 1891 the Frenchman Blondlot transmitted Hertz's waves along two straight and parallel wires, a Lecher guide system. After reflection, the waves created a standing wave system. Observing the nodal points Blondlot determined the wavelength. The frequency was known, and using Eq. (1) he obtained:

$$295\,000 \pm c = 305\,000 \text{ km/sec}$$

At this time, however, one was very uncertain as to the ratio between the velocities in vacuum and along the wires. Gutton solved this problem in 1911 by aid of the Kerr cell, making possible light variations of a frequency equal to that applied to the Lecher system. In a Kerr cell, the light passes between two condenser plates, lowered into nitrobenzene. By the electric field between the plates, due to the directive action on the oblong dipole molecules, the fluid acquires optical double-refracting properties. As soon as

the field ceases, the molecules recover their random directions through the influence of their thermal movements. Placing the cell between an optic polarizer and a normally oriented analyzer, the light intensity leaving the combination, within certain limits, is directly proportional to the voltage applied to the condenser. The voltage may be that from a high-frequency radio transmitter.

Later on Gutton's compatriot Mercier derived a theoretical formula for the ratio between light and the velocities of guided waves. Using a valve oscillator for the high-frequency voltage on a Lecher system and applying his formula to the result, he obtained, in 1921.

$$c = 299\,782 \pm 30 \text{ km/sec}$$

In the 1870's, Newcomb had introduced a revolving reflecting multi-surface prism in place of Foucault's mirror. Michelson improved the system further, first in 1879 and finally at Mt. Wilson in 1926, his most accurate measurement. During the time required for the light to cover the distance of 35 km and back, the prism turned the next of its 12 surfaces in place for reflection. Only for exactly correct rotational speed the position of the image of the suddenly illuminated distant reflector in the field of sight was independent of the direction of rotation. The comparison of phase may be said, here too, to have occurred at "coincident maxs," and the high accuracy was due to the great displacement of the image for a turn of the revolving prism. Michelson's value was

$$c = 299\,796 \pm 4 \text{ km/sec}$$

He overlooked a group correction of $\pm 2 \text{ km/sec}$.

Michelson, Pease and Pearson planned a determination in vacuum. It was completed by Pease and Pearson after Michelson's death in 1931. By multiple reflection in a 1-mile evacuated pipe, the light path was 10 miles. Due to the pipe, the geometry of the measuring device was considerably less symmetrical than in the case of the Mt. Wilson determination. The experiment was much talked about and the result was considered of high quality.

$$c = 299\,774 \pm 11 \text{ km/sec}$$

In 1928 the German scientists Karolus and Mittelstaedt performed the first direct determination using a Kerr cell. Their result was

$$c = 299\,778 \pm 20 \text{ km/sec}$$

Here too the group correction seems to have been overlooked.

Now Michelson's 1926 result was regarded as doubtful, and in 1940 Anderson, an American, tried to arrive at a decision. He used a Kerr cell. For phase comparison a photomultiplier received light from two nearby mirrors, the second of them at a somewhat greater distance in order to obtain intensity maxima from the one mirror coincident with minima from the second. The alternating photo-current then was equal to zero. Thereupon, the second mirror was moved away

some 170 meters, and the distance was adjusted anew to yield a photo-current equal to zero. After the known mirror displacement, the light's travel time had increased an even multiple of the intensity period, known from the frequency. Anderson's value:

$$c = 299\,776 \pm 14 \text{ km/sec}$$

Thereby the Michelson 1926 value was ruled out. Anderson carefully considered the group correction. Possibly, Anderson on occasions of his apparatus yielding values very different from the evacuated pipe result, might have felt particularly called upon to search for error sources and in that way unconsciously influenced the result. Or it might have been pure chance. In any case, his value superceded the pipe result.

Anderson's value was used for radar systems. Thereby a microwave transmitter emits short pulses (10⁻⁶ second) which after distant reflection and return are received again. On the screen of a cathode ray tube the rapid sweep of the ray is marked by emitted and received pulses. The difference of mark positions and the sweep speed yields the pulse travel time. By knowing c the distance is obtained. "Oboc" (0.1-meter wave) and "Shoran" (1-meter) applied to known distances gave low values. Was the c -value used too low?

In 1947 Jones and Conford used Oboc in a manner opposite to its usual operation for the determination of c over known distances and got

$$c = 299\,782 \pm 25 \text{ km/sec}$$

In the case of Shoran the main pulse-giving radar station is in an aircraft traversing the known straight distance between two points. In order to get strong echoes, there are radar slave stations at the points. Immediately after receiving the pulses, the slave stations reemit them on a slightly different wavelength. By that the main station receiver is not disturbed by its own transmitter. The distances to the two slave stations are continuously registered, and the shortest distance and also that used are obtained at the moment of transversing. A typical distance is 300 km. By careful treatment of Shoran results, Aslakson in 1949 obtained a velocity value

$$c = 299\,792.3 \pm 2.3 \text{ km/sec}$$

In 1951 he used "Hiran," by which errors from varying signal strengths are avoided, and obtained

$$c = 299\,794.2 \pm 1 \text{ km/sec}$$

Meanwhile Essen attacked the problem in a quite new manner by his indirect determination using a cavity resonator. Microwave guides may be circular tubes of sufficient diameter to let the waves through. If such a tube, whose length is an even multiple of half the wavelength, is closed by plane reflecting covers, the oscillating energy supplied remains in the cavity as a standing wave. This state only occurs in case of an exact, definite resonance frequency. In practice, there are several adjacent resonance frequencies depending

on remaining oscillation states, e.g., including different multiples over a diameter or over several symmetrically orientated diameters. Sarbacher and Edson have derived the exact mathematical expression for all these resonance frequencies as functions of the tube length, tube diameter and the inside wave velocity. Essen and Gordon-Smith very carefully measured length, diameter and frequency and used an evacuated cavity. By calculations, they found the vacuum value c . Their result, in 1947, was:

$$c = 299\,792.2 \pm 4.5 \text{ km/sec}$$

In 1949 Essen repeated the determination using a cavity whose length could be varied by an inserted movable plunger. By the dependence of the results on the cavity length, systematic errors could be rejected. The final value was

$$c = 299\,792.5 \pm 1 \text{ km/sec}$$

Applying current practices, the error limits of 1 km/sec may be reduced perhaps by half.

At this time, Bergstrand performed direct experiments using visible light. The alternating voltage, supplied by a 10-Mc/sec radio transmitter, coincidentally fed Kerr cell and photo tube. In place of "coincident max's" the phase comparison was carried out in moments of light pulses reaching half of maximum intensity. Then the photo-current was strongly dependent on the distance to the reflector. By low-frequency phase shift of the emitted light intensity modulation (interchange of maximum and minimum), there were periodically two photocurrents, and by exactly chosen distance, they balanced each other to an O-current on the control instrument. In this way, by known displacement of the reflector through several successive such O-points the wavelength of intensity variation, i.e., the group length L_K , could be determined. The group velocity was obtained from $u = vL_K$, reduced to c by Eqs. (6) and (9). Besides some preliminary results from 1947-48, the 1950 value was:

$$c = 299\,793.1 \pm 0.3 \text{ km/sec}$$

Under the name of "Geodimeter," Bergstrand's instrument is used all over the world for measuring distances with high accuracy, c being considered as known. The error in 30 km need not exceed 5 cm. When the geodimeter was used to check the rocket-camera positions around Cape Kennedy, the accuracy turned out to be still better.

Using the geodimeter on known distances, of course, one can obtain c . The experience from recent, improved models now shows that the just related value of 1950 is slightly too high. In 1953 Mackenzie on the Ridge Way and Caithness base lines obtained

$$c = 299\,792.3 \pm 0.5 \text{ km/sec}$$

In 1959 a Russian geodimeter determination on 6 base lines yielded

$$c = 299\,792.5 \pm 0.1 \text{ km/sec}$$

Almost identical results were obtained on Czech and Bavarian base lines. In 1955 Velitschko constructed a Kerr apparatus (SWW-1) for distance measurements. There was a Kerr cell on the receiving end also. The phase indication was visual. On base lines, the SWW-1 yielded:

$$c = 299\,792.7 \pm 0.3 \text{ km/sec}$$

Intended for the same purpose, but less accurate than the geodimeter, are instruments using microwave (10 cm.) radiation sources, such as Wadley's Tellurometer of 1957. By this method, a moving wave system is created between two equal instruments, having slightly different measuring frequencies (10,000 and 10,001 Mc/sec). The phase comparison is done by the low-beat frequency of 1000 cps.

Generally, perhaps the hitherto most accurate c determination is that by Froome. In 1950 he started preliminary measurements and in 1958 he used a klystron transmitter delivering harmonics of 0.4 cm wavelength. By guiding pipes the microwave emission was divided into two equal parts. The two pipes terminated in transmitting horns supplied with lenses to form the front surface of the emitted wave as plane as possible. The pipes were bent 180° each in order to get the horns directed opposite to each other. The distance between the horns was 6 to 14 meters. Between the horns there was created a standing wave system, where the nodal points were observed by aid of a movable receiving detector. The displacement of the detector was measured interferometrically. In this way the microwave length was determined with great accuracy. By carrying through the determination for different horn distances, systematic errors were rejected. These errors may depend on disturbing reflections or on the wave fronts not being sufficiently plane or of known shape. The frequency was controlled by aid of an atomic clock. The result of 1958 was

$$c = 299\,792.5 \pm 0.1 \text{ km/sec}$$

or identical to the Russian and other recent geodimeter results. By use of a maser, Froome expects to realize an analogous measurement with visible or infrared light.

A summary of determinations of recent years thus indicates a c -value very close to 299 792.5 km/sec.

Finally, there is an indirect method which does not give such high accuracy: The exactly known frequency of an atomic clock is the ground rotational molecular frequency with quantum number $= 1$ of some diatomic gas. From the quantum spectral formula of the rotational line series, one obtains the frequency at high quantum numbers of visible or infrared light, where the wavelength is known with great accuracy. The connection between wavelength and frequency yields c , and in 1955 Rank, Bennet and Bennet obtained the value $299\,791.9 \pm 2.2 \text{ km/sec}$.

VIBRATION

In physics, the term "vibration" is used for any sustained motion, characteristic of a finite system, in which each particle or element of the system moves to-and-fro about an equilibrium position. In the simplest situation, such a motion possesses a unique "periodic time." The inverse of this quantity, the "frequency," is the number of complete to-and-fro excursions per unit time.

It might appear that reference to a finite system in the above definition is gratuitous: infinite systems are mere figments of the theorist's imagination; only finite systems have real existence. Nevertheless, the emphasis is intentional. As will appear, the natural frequencies of vibrating systems depend, in general, on the size (spatial extent) of such systems.

In order to introduce the subject, the motion of a simple pendulum will first be considered—though, strictly, this motion does not fulfil the conditions that have been specified for vibrations: the natural frequency is not characteristic of the pendulum alone, it depends also on the acceleration due to gravity at the place where the pendulum is used. It is usual to speak, therefore, of the oscillations of a pendulum, rather than of its vibrations.

An ideal simple pendulum consists of a very small massive bob (of mass m) attached to one end of a perfectly flexible massless string (of length l), the other end of the string being fixed to a rigid support. In equilibrium, the pendulum hangs vertically; when the bob is displaced sideways and let go, the pendulum oscillates in a vertical plane. In such motion, the string, being massless and under tension, remains straight, and the whole system may be regarded as rigid. An ideal simple pendulum, then, is effectively a rigid body of moment of inertia ml^2 about its axis of oscillation, and, the moment of the weight of the bob about this axis being $mg l \sin \theta$, when the angular displacement is θ , the equation of motion is

$$ml^2 \ddot{\theta} = -mg l \sin \theta$$

Here g is the acceleration due to gravity. For small displacements, therefore,

$$\ddot{\theta} = -(g/l)\theta \quad (1)$$

and, under this limitation

$$\theta = \alpha \cos\left(2\pi \frac{t}{\tau} + \delta\right) \quad (2)$$

α and δ being arbitrary constants, and τ , the periodic time, being given by

$$\tau = 2\pi(l/g)^{1/2} \quad (3)$$

Equations (2) and (3) provide the general solution of Eq. (1). On examination, they will be seen to represent an oscillation in angle, between limits $-\alpha \leq \theta \leq \alpha$, of periodic time τ which is independent of α . The constant δ specifies the displacement at the instant arbitrarily chosen as the zero of time; it is referred to as the "phase angle" of the motion related to this choice of time zero. The constant α is referred to as the (angular) amplitude of the oscillation. The fact that the periodic time (or frequency), in pendulum motion, is independent of amplitude (for small amplitudes) was first discovered empirically by Galileo, in 1581. A similar result is true for any motion (in angle, or any other coordinate) in which the acceleration towards the equilibrium position is proportional to the displacement, as required by Eq. (1). Motion having this character is "simple harmonic motion."

Pendulum motion has been considered in some detail because, historically, it was the first example of simple harmonic motion to be understood. For present purposes, however, more direct relevance might be seen in the motion of a load suspended by a helical spring. If such a load is displaced vertically, it executes simple harmonic motion about its position of EQUILIBRIUM. The extra upwards force acting on the load (by Hooke's law) being proportional to the extra extension of the spring, the acceleration of the load towards equilibrium is proportional to the displacement, as is required. But it is not easy, in practice, to approximate to the ideal of a massless spring supporting a massive load, and a theoretical account of the oscillations of a loaded spring which does not take count of the mass of the spring is oversimplified.

Simple harmonic motion is referred to as "isochronous" because, in a given case, the periodic time is the same whatever the amplitude. If the vibratory motion of an extended system were not similarly isochronous, there would be little point in claiming, as has already been done, that such motion, at its simplest, may be characterised by a periodic time which is unique. But the fact is that we have ample experience of real physical systems whose vibrations are of this character: it is natural to conclude, therefore, that the motion of each particle or element of a system so vibrating is simple harmonic motion. That is the reason why simple harmonic motion

has been considered in its own right, as a preliminary to the discussion of vibratory motion.

In vibratory motion, the restoring forces responsible for the individual motions of the constituent elements of a vibrating system may arise from tensions externally applied to the system (as with stretched strings and membranes), from elastic stresses developed internally as the system is deformed (as with rods vibrating longitudinally, transversely or torsionally; with air columns in organ pipes; with thin plates of regular shape), or occasionally in other ways (surface tension forces, for example are involved in the pulsation vibrations of thin films of liquid).

The simplest system of the first type is the stretched string. Imagine a uniform string, of length l and total mass ml , stretched under tension T between rigid supports. Let rectangular axes OX , OY be taken, along and at right angles to the length of the string in its undisturbed state, and let us consider possible transverse vibrations of the string in the XY plane. Suppose that all displacements (y) are very small compared with l , so that any over-all increase in the length of the string is negligible, and the tension may be regarded as constant throughout. Under these conditions, imagine that the string is in steady vibration, and at an arbitrary instant, let the transverse displacement vary along the length of the string as represented by the expression $y_0 = f(x)$. The instantaneous value of the curvature of the "displacement profile" of the string, at x , being given by $f''(x)$, the instantaneous magnitude of the force per unit length of the string about x is $Tf''(x)$. Under these imposed conditions, this force is essentially at right angles to OX and in the direction of y increasing—and, as a result, the acceleration of the element of the string around x is $(T/m)f''(x)$, instantaneously. Only if this acceleration is proportional to the instantaneous displacement at x , and if the proportionality constant is independent of x , will each element of the string execute simple harmonic motion of the same period—and only then will the postulated vibration of the string as a whole be well-defined. For such sustained motion, therefore, the necessary condition is

$$(T/m)f''(x) = -\mu f(x) \quad (4)$$

where μ is a constant, independent of x . When μ has been evaluated, ν , the frequency of the vibration, will likewise be known, for, in this case [compare Eqs. (1) and (3)]

$$\nu = \mu^{1/2}/2\pi \quad (5)$$

Now, the general solution of Eq. (4) is

$$f(x) = A \sin\left\{\left(\frac{\mu m}{T}\right)^{1/2} x + \epsilon\right\}$$

but, because the string is fixed at its two ends, so that $f(0) = f(l) = 0$,

$$\epsilon = 0$$

and

$$\left(\frac{\mu m}{T}\right)^{\frac{1}{2}} l = n\pi$$

n being a positive integer. For ν , therefore, we have [see Eq. (5)]

$$\frac{n}{2l} \left(\frac{T}{m}\right)^{\frac{1}{2}}$$

and, for $f(x)$,

$$f(x) = A \sin \frac{n\pi x}{l}$$

Again, since each element of the string executes simple harmonic motion of frequency ν , we have the following general expression for the displacement (y) of any element of string, given as a function of x , and the time t , namely

$$A \sin \frac{n\pi x}{l} \cos \frac{n\pi}{l} \left(\frac{T}{m}\right)^{\frac{1}{2}} t \quad (6)$$

Taking account of all possible values of n , Eq. (6) represents the whole series of simple modes in which the stretched string may vibrate. Generally, these modes are referred to as the "normal modes" of the system. Because the frequencies of these normal mode vibrations are the successive integral multiples of a basic frequency, $(1/2l)(T/m)^{\frac{1}{2}}$, they are said to form a "harmonic series," and the vibrations themselves are often described as the "first harmonic," "second harmonic," and so on. Alternatively, the first harmonic may be referred to as the "fundamental mode," the second harmonic as the "first overtone," and similarly throughout the series. It will be seen, from Eq. (6), that in the fundamental mode, the only points in the string which remain permanently at rest are the ends of the string; in the n th normal mode, in general, there are $(n-1)$ other points of permanent rest ("nodes") equally spaced between the two ends. Mid-way between the nodes are the points of greatest amplitude of motion ("anti-nodes").

By restricting consideration to the case in which the shape of the displacement profile of the string is the same at all instants throughout the vibration (being represented by $y_0 = f(x)$, above), we made certain that only normal mode vibrations should emerge from our analysis. But more complex sustained motion is possible in which the shape of the displacement profile continuously changes. To sustained motion of this general type, no single periodic time may be assigned. On the other hand it may be shown that every such motion may be regarded as resulting from the superposition of normal mode vibrations, the amplitudes and phases of the various modes being uniquely determinable in terms of the details of the actual motion as observed over a sufficient interval of time. From this point of view, the potentialities of the system

for sustained motion are completely given in Eq. (6) describing the normal modes.

With essentially linear systems, such as strings and rods and organ pipes, when the conditions at the two ends of the system are the same (as they are with the stretched string), and there is no internal constraint, the normal modes in general constitute a harmonic series; when the end conditions are different (as in a pipe which is closed at one end and open at the other) in general the even-numbered harmonics are not represented. In all cases, however, the theorem concerning the decomposition of the most complex sustained motion in terms of the normal modes applies.

As an example of elastic vibrations, we consider, briefly, the transverse vibrations of a thin, uniform rod, which is clamped at one end. For a displacement profile of arbitrary shape, the elastic forces brought into play across any section of the rod are proportional to the displacement of the rod at that section, and the unbalanced restoring force acting on a small finite element of the rod is similarly proportional to its displacement. But the proportionality constant relating restoring force per unit length to displacement will, in general, vary along the rod. Only for displacement profiles of certain shapes will this constant be the same over-all. These are the shapes of displacement profile corresponding to the normal mode vibrations, and it is the object of theory to identify them and to deduce the corresponding frequencies. Even an approximate theory is complicated; all that can be done here is merely to quote the ratios of the frequencies of the first three normal mode vibrations, namely 1:6.27:17.55. Very clearly, the normal modes in this case do not constitute a harmonic series: in musical parlance, the first overtone is some $2\frac{1}{2}$ octaves higher than the fundamental.

Throughout the above discussions, actual physical situations have been consistently idealized, in that it has been assumed, implicitly, that all periodic motion is sustained indefinitely. In fact, all such motion, unless energy is continually supplied from outside, gradually loses amplitude and dies away. This process is referred to as "damping," and the dissipation of energy which is its essential feature is generally, in mechanical systems, attributable to friction. Detailed consideration of damping is, however, beyond the scope of this article.

VISCOELASTICITY

Viscoelasticity is a material property possessed by solids and liquids which, when deformed, exhibit both viscous and elastic behavior through simultaneous dissipation and storage of mechanical energy. The *material constants* linking stress and strain in the theory of elasticity become *time-dependent material functions* in the constitutive equations of viscoelastic theory. At sufficiently small (theoretically infinitesimal) strains the behavior of viscoelastic materials is well described by the *linear theory of viscoelasticity* epitomized by the celebrated *Boltzmann superposition principle*. Expressed in its simplest form

$$\sigma(t) = \int_0^t Q(t-u)\epsilon(u) du$$

$$\epsilon(t) = \int_0^t U(t-u)\sigma(u) du$$

it states that the stress (or strain) at time t under an arbitrary strain (or stress) history is a linear superposition of all strains (or stresses) applied at previous times u multiplied by the values of a weighting function $Q(t)$ [or $U(t)$] corresponding to the time intervals $t-u$ which have elapsed since imposition of the respective strains (or stresses).

Considerable simplification of the viscoelastic relations is achieved by mapping them from the real t axis into the complex s plane through the Laplace transformation. The resulting transforms in s may be manipulated algebraically and then inverted to regain the time-dependent form. Thus the above convolution integrals become

$$\sigma(s) = Q(s)\epsilon(s) \quad \epsilon(s) = U(s)\sigma(s)$$

and $Q(t)$ and $U(t)$ can be seen to be the material functions representing the response to a unit impulse of strain or stress. The unit step response functions, the material functions under constant strain ϵ_0 and constant stress σ_0 , are the *relaxation modulus* and *creep compliance*, obtained as

$$G(t) = \sigma(t)/\epsilon_0 = \mathcal{L}^{-1} Q(s)/s$$

$$J(t) = \epsilon(t)/\sigma_0 = \mathcal{L}^{-1} U(s)/s$$

where \mathcal{L}^{-1} denotes inversion of the transform. For sinusoidal steady state strain $\epsilon(\omega)$ and stress $\sigma(\omega)$, there result the *complex modulus* and *complex compliance*

$$G^*(\omega) = \sigma(\omega)/\epsilon(\omega) = [Q(s)]_{s=i\omega}$$

$$J^*(\omega) = \epsilon(\omega)/\sigma(\omega) = [U(s)]_{s=i\omega}$$

whose real and imaginary parts are the *storage modulus* $G'(\omega)$, *storage compliance* $J'(\omega)$, *loss modulus* $G''(\omega)$, and *loss compliance* $J''(\omega)$. Their ratio is the *loss tangent*

$$\tan \delta(\omega) = G''(\omega)/G'(\omega) = J''(\omega)/J'(\omega)$$

Any of the above functions (or any other that may be derived, e.g., for constant rate of strain), if known over a sufficiently extended time scale

(or, equivalently, over a sufficient range of frequencies), provides complete information on the viscoelastic properties of a homogeneous isotropic material. As formulated above, the equations refer to deformation in simple shear. When dealing with combined stresses, as in viscoelastic stress analysis, the tensorial character of stress and strain must, of course, be taken into account. The equations for other types of deformation, e.g., dilatation or uniaxial extension, are analogous to those for shear. The relations between the frequency-dependent viscoelastic functions in shear, extension, and dilatation are the same as those between the elastic constants, while for the time-dependent functions these relations are valid between the s -multiplied Laplace transforms. Thus the relaxation modulus in extension $E(t)$ is related to $G(t)$ through the *time-dependent Poisson's ratio* $\nu(t)$ by

$$E(s) = 2G(s) [1 + \nu(s)]$$

and for $\nu(t) = 1/2$, $E(t) = 3G(t)$. Data obtained in shear and extension on incompressible bodies are thus readily combined. Moreover, if a viscoelastic function can be formulated analytically, it can be converted into any of the others, allowing combination of measurements made under different stress or strain histories. Use is made of this to extend the experimentally accessible time scale. Thus at short times, dynamic (frequency-dependent) measurements are more convenient than transient (time-dependent) measurements, and *vice versa* for long times.

Another important extension of the time scale is available through *time-temperature superposition*. An increase in temperature generally shortens the time necessary for the molecular rearrangement processes responsible for viscoelastic behavior. If all such processes are affected by temperature in the same way, the material is *thermorheologically simple*, and a change in temperature simply shifts the viscoelastic functions along the logarithmic time or frequency axis. For polymers (the typical viscoelastic materials) above the *glass transition temperature* (at which main chain motion effectively ceases), the shift factor a_T is given by an equation of the form (WLF equation)

$$\ln a_T = \frac{c_1(T - T_0)}{c_2 + T - T_0}$$

where T_0 is a suitably chosen reference temperature, and c_1 and c_2 are constants. Measurements made at different temperatures can thus be combined to yield a single *master curve*.

Interconversion of the viscoelastic functions is facilitated by the introduction of *spectral distribution functions*. The spectral functions may be derived conveniently by rewriting the Boltzmann superposition principle, given above as an integral operator equation, in the form of the *differential operator equation*:

$$[\Sigma p_m D^m] \sigma(t) = [\Sigma q_m D^m] \epsilon(t)$$

where $D' = d'/dr$. The Laplace transformation leads to

$$Q(s) = 1/U(s) = \sum q_m s^m / \sum p_m s^m$$

a definition of $Q(s)$ and $U(s)$ which is readily linked with the useful representation of viscoelastic behavior by *models* consisting of series-parallel combinations of springs (elastic or storage elements) and dashpots (viscous or dissipative elements). A parallel combination (Voigt model) is characterized by a *retardance* $U(s) = 1/(G + \eta s) = J/(1 + \lambda s)$, where $\lambda = \eta/G$ is the *retardation time*, η signifies viscosity, and $J = 1/G$. A series combination (Maxwell model) is characterized by a *relaxance* $Q(s) = 1/(J + 1/\eta s) = G\tau s/(1 + \tau s)$ where $\tau = \eta/G$ is the *relaxation time*.

Through the *combination rules*: "relaxances add in parallel, retardances add in series," $Q(s)$ and $U(s)$ are readily derived from a given more complex model as illustrated below.

These models are *conjugate*, i.e., with suitable choices for the parameters, they describe the same viscoelastic material. Representation of viscoelastic behavior by a (small) finite number of elements is often inadequate. Molecular theories of polymer behavior lead to models with an infinite number of parameters, characterized by a *discrete distribution* (or *line spectrum*) of *relaxation* or *retardation times*. These distributions are normally so closely spaced that they cannot be resolved experimentally. One can therefore define *continuous distribution functions*

$$Q(s) = \int_0^\infty G(\tau) \frac{\tau s}{1 + \tau s} d\tau = \int_0^\infty H(\tau) \frac{\tau s}{1 + \tau s} d\ln \tau$$

$$U(s) = J + \int_0^\infty J(\lambda) \frac{d\lambda}{1 + \lambda s} = 1/\eta s$$

$$J = \int_0^\infty L(\lambda) \frac{d\ln \lambda}{1 + \lambda s} = 1/\eta s$$

where $G(\tau)$ and $J(\lambda)$ are distributions of relaxation and retardation times respectively, and $H(\tau) = \tau G(\tau)$ and $L(\lambda) = \lambda J(\lambda)$ are their counterparts on the more convenient logarithmic time scale. The spectral functions may be derived from experimentally determined curves of the viscoelastic functions through any of several approximation methods.

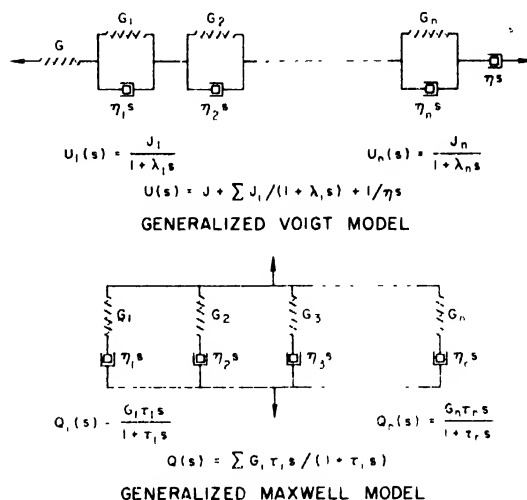

FIG. 1.

The various viscoelastic functions are illustrated below on the example of an uncross-linked amorphous polyvinyl acetate with a molecular weight of about 300 000. Data obtained in extension and shear at different temperatures were combined and interconverted. The functions are grouped to display their qualitative symmetries.

FIG. 2.

Singling out the relaxation modulus for a broad interpretation of the viscoelastic behavior of an uncross-linked polymer, one sees that at short times (in the *glassy region*), the modulus approaches an asymptotic value, the *glass modulus*. It then drops through the *glass-to-rubber transition region* and levels out somewhat in the *plateau region* reflecting the effect of molecular entanglements. At still longer times, it decays to zero through the *terminal region*. For cross-linked networks this region is absent (if there is no chemical degradation). In this case, the flow term $1/\eta s$ is missing from $U(s)$ above; an additive constant, the *equilibrium modulus* G_e , characterizing the (level) *rubbery region*, appears in $Q(s)$.

Current efforts in the field of viscoelasticity are directed chiefly towards the development of nonlinear (large deformation) theory, theories of anisotropic and inhomogeneous (semicrystalline and filled) systems, the solution of viscoelastic boundary problems (viscoelastic stress analysis), and the explanation of viscoelastic behavior on the molecular level (molecular theories).

VISCOSITY

Materials in general show two broad kinds of behavior with regard to their reaction when subject to an applied force. In one type, they deform until a position of equilibrium is reached, when no further change of shape takes place. Many solids show this kind of behavior. Alternatively, there is no permanent resistance to change of shape, and continuous deformation takes place for as long as the force is applied. The material is said to flow. Substances possessing this property are called fluids and may generally be thought of as either liquids or gases. The class also includes some materials, such as glass and pitch, which at

room temperature exhibit many of the characteristics normally associated with solids. When flow takes place in a fluid, it is opposed by internal friction arising from the cohesion of the molecules. This internal friction is the property of the fluid known as *viscosity*. It is clearly of great importance in many contexts; we may think, for example, of the flow of blood in the body, the flow of oil in pipe lines, the working of molten glass, and the process of lubrication. It may be used in the discrimination between streamlined and turbulent flow. It is also a useful property in providing information about the structure of complex organic molecules.

Definitions and Units. The formal definition of viscosity arises from the concept put forward by Newton that under conditions of parallel flow, the shearing stress is proportional to the velocity gradient. If the force acting on each of two planes of area A parallel to each other, moving parallel to each other with a relative velocity V , and separated by a perpendicular distance X , be denoted by F , the shearing stress is $\frac{F}{A}$ and the velocity gradient, which will be linear for a true liquid, is $\frac{V}{X}$.

Thus

$$\frac{F}{A} = \eta \cdot \frac{V}{X}$$

The constant η is known as the viscosity coefficient, dynamic viscosity, or viscosity of the liquid. The unit, expressed in dyne second per square centimeter, is known as the "poise," after Poiseuille who worked on viscosity in the early part of the nineteenth century. For practical purposes it is often more convenient to use a smaller unit, known as the centipoise, equal to a hundredth of a poise. It is useful to note that water at room temperature has a viscosity of approximately 1 centipoise. In many applications of viscometry, it is useful to note another quantity, called the kinematic viscosity, which is obtained by dividing the dynamic viscosity by the density. It is frequently denoted by the Greek letter ν , and the unit in which it is expressed is the "stokes," after Sir George Stokes, another pioneer worker in viscometry. In practical viscometry, viscosity is sometimes expressed in seconds; this is a measure of the time for a prescribed quantity of liquid to flow through a tube or aperture of defined dimensions.

In considering many problems of fluid motion, an important non-dimensional quantity is vd/ν , where v is the velocity of the fluid, ν its kinematic viscosity, and d a linear dimension, such as the diameter of a tube. This quantity is known as the Reynolds' number; when it is less than about 1000, flow is generally streamlined, whereas at values over 1000 it is turbulent.

Values for the viscosity of a number of common substances are given in Table 1.

Methods of Measurement. In measuring viscosity in the absolute sense, it is necessary to be

TABLE I. COEFFICIENT OF VISCOSITY IN POISES
(APPROXIMATE VALUES)

Water at 20°C	0.010
Mercury at 20°C	0.015
Carbon tetrachloride at 20°C	0.009
Olive oil at 20°C	0.84
Glycerine at 20°C	8.3
Golden Syrup at 20°C	1000
Glass at melting temperature	10 ³
Glass at working temperature	10 ⁷
Glass at annealing temperature	10 ¹³
Air at 0°C	0.00017
Carbon dioxide at 0°C	0.00014
Steam at 100°C	0.00013
Pitch at 15°C	10 ¹⁰

able to use the basic relationship between shearing stress and velocity gradient in order to derive a relationship between the measurable quantities involved in flow in an apparatus of a particular shape. For example, it can be shown that the volume Q of a liquid of viscosity η flowing per unit time through a tube of length l and internal radius a , when the pressure difference between the ends is P , is given by

$$Q = \frac{\pi Pa^4}{8l\eta}$$

Capillary viscometers enable all the variables in this equation to be measured and the viscosity to be determined.

Similarly, a viscometer can be constructed in which one cylinder rotates inside another with the liquid under test in the annular space between the two. Measurement of the angular velocity and the applied torque, together with a knowledge of the dimensions of the apparatus, enables the viscosity to be calculated.

Another method involves the measurement of the rate of fall of a sphere in a column of liquid. If the liquid has viscosity η and density ρ , and the sphere has radius r and density σ , then the velocity of fall is

$$v = \frac{2gr^2(\sigma - \rho)}{9\eta}$$

a relationship commonly known as Stokes's law.

There are also a number of empirical methods that can be used to obtain comparative values, the instruments being calibrated by using liquids of known viscosity.

Variation with Temperature. The viscosity of liquids decreases rapidly with increasing temperature. For example, the viscosity of molten glass may be halved by raising the temperature 30°C. On the other hand, the viscosity of gases increases with temperature. This feature is of practical importance in two senses. In all methods of measurement strict temperature control is necessary and when results are quoted, it is essential to state the temperature to which they refer.

The variation of viscosity with temperature is of great significance in the problem of lubrication, where oils may have to operate over widely

different conditions. So-called viscostatic oils have a low temperature coefficient and can thus be used over a wide temperature range. As an indication of this property, the oil industry uses an empirical number known as the "viscosity index"; the higher the viscosity index, the less is the variation of viscosity with temperature.

Molecular Weight Determinations. The viscosity of organic materials in solution was suggested by Staudinger as a useful index of their molecular structure, since the flow properties would be influenced by the size and shape of the molecules. For example, some high polymers give appreciable increases of viscosity even at low concentrations on account of the effect of randomly coiled long-chain molecules. Generally speaking, the higher the molecular weight, the greater is the increase in viscosity for a given weight in the solution. The values of molecular weight obtained by this method are not absolute, but they depend on the establishment of empirical relations by measurements on substances of known molecular weight in a given series (see MOLECULAR WEIGHT).

Non-Newtonian Systems. A large number of industrially important materials do not obey the simple Newtonian relationship between shearing stress and shearing rate. In some cases the viscosity varies with the shearing rate, and in others, it varies with time when the shearing rate is constant. An important group of such materials are known as thixotropic substances—they become thinner when stirred. Paint, suspensions of clay in water, and many other substances behave in this way, and the property has considerable industrial significance. In the case of paint, for example, the low viscosity when brushed in a thin film makes for easy application, whereas the high viscosity under low shearing stresses enables the film to be retained on vertical surfaces. Some substances thicken up on stirring, and there are a number of other classes of behavior (e.g. VISCOELASTICITY) that constitute departure from Newtonian laws. The study of such anomalous systems is an important branch of modern RHEOLOGY.

VISION AND THE EYE

The meaningful experience of vision requires light, the eye, and a conscious observer (animal or human) having an intact *visual system*. In its gross aspects, the visual system includes the eyes, the *extraocular muscles* which control eye position in the *bony orbit* (eye socket), the optic and other nerves that connect the eyes to the brain, and those several areas of the brain that are in neural communication with the eyes. This summary will stress the informational aspects of human vision; it should be realized however that no visual system could function without its *protective mechanisms* (tears and eyelids, especially) or if its normal metabolism (mediated through the vascular supply of eye and brain) were seriously interfered with.

The visual system is particularly well adapted for the rapid and precise extraction of spatial information from a more-or-less remote external world; it does this by analyzing, in ways that are as yet imperfectly understood, the continuously changing patterns of radiant flux impinging upon the surfaces of the eyes. Much of this light is reflected from objects which must be discriminated, recognized, attended to, and/or avoided in the environment; this ability transcends enormous variations in intensity, quality, and geometry of illumination as well as vantage point of the observer. A block diagram of the visual system is given in Fig. 1.

Although image formation in the eye is importantly involved, the analogy between eye and photographic camera has been badly overworked and tends to create the erroneous impression that little else is needed to explain how we see. Image formation is greatly complicated by the movement of the eyes within the head, and of both eyes and head relative to the external sea of radiant energy. Such visual input is ordinarily sampled by discrete momentary pauses of the eyes called *fixations*, interrupted by very rapid ballistic motions known as *saccades* which bring the eyes from one fixation position to the next. Smooth movements of the eyes can occur when an object having a predictable motion is available to be followed. A large body of evidence suggests that the visual input is processed by the brain in "time frames" of about 100 msec, although the

peripheral parts of the visual system operate with much shorter time constants than this.

Each eye controls many important functions within one mobile housing: it is a device to form an image upon a vast array of light sensitive *photoreceptors*, but it also contains systems to dissect, encode, and transmit information derived therefrom. A crosssection of the human eye is shown in Fig. 2. The primary refracting surface is the *cornea*, a complex yet transparent structure which admits light through the anterior part of the outer surface of the eye. The *iris* contains muscles which alter the size of the entrance port of the eye, the *pupil*. The *crystalline lens* has a variable shape, under the indirect control of the *ciliary* muscle. Since it has a refractive index higher than the surrounding media, it gives the eye a variable focal length, allowing *accommodation* to objects at varying distances from the eye. The iris muscles and the ciliary muscle, known collectively as the *intraocular* muscles of the eye, are controlled by impulses having their origins in separate but interacting centers in the brain stem. These brain centers also receive nerve impulses from the eye. These loops, and those involving the extraocular musculature and thus eye position, have some of the properties of nonlinear servosystems, and have been actively investigated as such.

Much of the remainder of the eye is filled with fluids and materials under pressure, which help the eye maintain its shape. The *aqueous humor*—thin, watery, and continuously being replaced—fills the *anterior chamber* between cornea and lens. The *vitreous humor*—thinly jellylike and of very low metabolism—fills the majority of the eye's volume. The image produced through these structures is formed upon the *retina* at the back of the eye. The retinal image is very small, because the eye itself is small and has a short posterior focal length of about 19 to 23 mm, depending upon accommodative state. The retinal image has a point-spread function on the order of two to three minutes of arc, corresponding to about 10μ on the retina for ideal conditions. These conditions include a 2 to 3 mm pupil, monochromatic light, optimal accommodation and a normal, young, and healthy eye. This quality approaches, but is somewhat worse, than that produced by diffraction-limited imagery

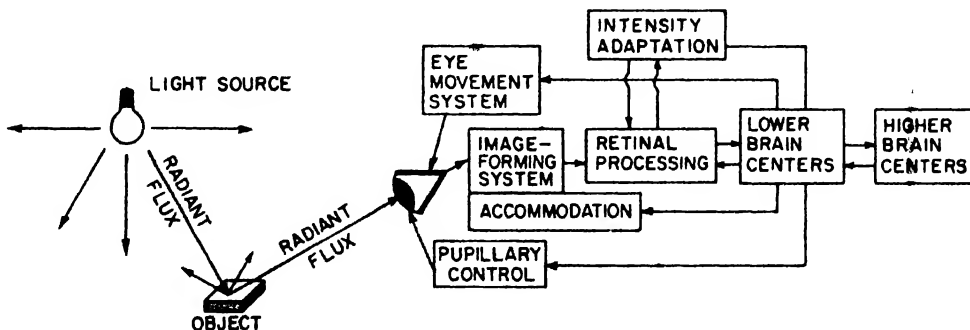

FIG. 1. Block diagram of the functional components of the visual system.

FIG. 2. Horizontal cross section of the right eye of the human.

in an ideal optical system. The retinal image is always in motion: even during the best efforts at steady fixation, there exists an irreducible tremor of the eye whose high-frequency components are in the 20 to 30 second-of-arc range, with larger drifting and saccadic movements up to 5 minutes of arc. It is possible to eliminate this residual motion by various optical techniques; such stabilization usually results in a total loss of vision, providing an elegant demonstration that the visual system responds primarily to *changes* in light patterns, rather than to steady states. Electrophysiological evidence from animals amply confirms this.

The *retina* is a thin structure of extreme complexity. It is considered embryologically to be a displaced part of the brain, and it is of clinical importance as the only part of the central nervous system that can be directly observed in the intact living subject. The receptors, the *rods* and *cones*, line the back surface of the retina, in immediate contact with a dark layer (the choroid) which helps to nourish the receptors and to prevent multiple reflection of light. There are about 125 000 000 receptors in each human eye, of which only about 5 per cent are cones. The cones are however of an importance disproportionate to their relative number: in particular there is a small central bouquet of about 2000 of them, located in a rod-free depression of the retina known as the *fovea centralis* where they are packed together into an hexagonal array having a density of about 150 000/mm²; these are capable of dissecting the finest details of the optimal retinal image. This process is aided by the lateral displacement of other retinal structures through which light must pass to reach the cone receptors. Moreover, this is the area of the retina where images have the highest

attention value and which "projects" to a disproportionately huge area of the visual brain; the extraocular muscles move the eye more or less automatically, in the act of fixation, to put objects of interest into this region where their details can be most critically appreciated, while the accommodative mechanism alters the shape of the lens to produce the sharpest possible image in this region. The cones, including those in the fovea, function only at high luminance levels (approximately, above .01 candela/m²), below which they are functionally blind and the rods take over. Thus the retina contains two systems intermixed: (a) the cone system (photopic), good for high-acuity vision, which also mediates all color vision; (b) the achromatic rod system, which has relatively poor spatial resolving power, but very high sensitivity.

The rods and cones are synaptically connected to the *bipolar cells*, which in turn relate to the *ganglion cells*, whose axons constitute the optic nerve fibers. There are also rich horizontal connections among the receptors, among the bipolar cells, and among the ganglion cells. In addition, there is a high degree of convergence: the 125 000 000 receptors ultimately feed into only 1 000 000 nerve fibers of the flexible optic nerve, which therefore constitutes the principal "bottleneck" of information flow in the visual system. The convergence ratio for the fovea is about 1:1, helping to preserve the high-detail vision of this region, while in the peripheral retina this ratio is many thousands to one, leading to high sensitivity at the sacrifice of resolving power.

The pathways from retina to brain are by no means independent, including those emerging from the central fovea. The horizontal interconnections are utilized to allow inhibitory processes to sharpen the "neural image" by a

process of border enhancement, but much more complicated preprocessing of information occurs also. It is abundantly clear that the brain does not receive a replica of what is on the retina, although a spatial isomorphism between retina and brain does exist; rather, the messages sent to the brain tend to carry information that is already processed in complex ways to make efficient use of the limited communications pathways between eye and brain in an adaptively significant manner.

Because the two eyes are located in slightly different places in space, a disparity of the two retinal images results. Rather than to produce a blurred or confused picture, this *retinal disparity* results in the appearance of *stereoscopic depth*. Such depth judgments are remarkably precise, consistent with the findings that all but the smallest eye movements and accommodative adjustments are highly correlated between the two eyes, and that neural units in the visual brain are precisely connected, by way of intermediate synapses, to optically corresponding areas.

The normal eye exhibits a large amount of chromatic aberration which is not normally noticeable. There are at least two reasons for this: (a) the cone receptors exhibit a directional sensitivity which reduces the visual effectiveness of light entering the marginal zones of the pupil; (b) the visual system has a remarkable capacity to adapt to systematic distortions of almost any kind which do not carry useful information from the external world. For example, observers learn with practice to compensate for the effects of gross visual displacement caused by prisms placed before the eyes, and are no longer able to see the chromatic fringes produced by such prisms. Removal of the prisms produces reappearance of chromatic fringes and an apparent displacement in the opposite direction. The explanation of such effects is not simple: in this example, the adaptation to displacement is probably kinesthetic rather than visual, but the adaptation to fringes is almost certainly confined to the visual system. Related to this are many entoptic phenomena that are seldom perceived: (a) the shadows of the retinal blood vessels, which are in front of the receptors; (b) the blind spot in the visual field, caused by the receptor-free optic disc, large enough to contain 200 images of the moon; (c) "floaters," usually shadows of debris in the vitreous humor, clearly visible if attended to against bright, uniform surfaces such as the sky; (d) fleeting specks of light probably caused by the movements of corpuscles within the retinal blood vessels; (e) Maxwell's spot, probably corresponding to the region of the macular pigment, and many others.

The initial nonoptical event in the visual process is the absorption of single light quanta by single molecules of visual photopigment, of which millions are located in each rod or cone. Under ideal conditions, as few as a half-dozen of these elemental events within fairly broad bounds of time and area, are sufficient to lead to a visual sensation. The visual photopigment contained in

the rods is *rhodopsin*, having a peak sensitivity at about 505 nm. It has been much studied and is found in most animals including man. Absorption of light by rhodopsin probably produces graded potentials at the receptors that trigger all-or-none nerve impulses by the time the ganglion cells are activated, if not before. The exact mechanisms whereby light absorption gives rise to receptor potentials (and these to nerve impulses), although under active investigation, cannot be said yet to be satisfactorily understood.

Color vision depends upon the existence of three classes of visual photopigment, all different from rhodopsin, housed in different proportions in different classes of cone receptors. When two fields of light that are physically different look exactly alike in color (*metameric matches*), it is probable that the rate at which light is being absorbed in the three classes of cone photopigment is the same from both fields, although this is not yet definitely established. The perception of color clearly involves the higher levels of the visual system as well.

Another important property of the eye is its adaptation to intensity by means of which the eye changes its gain and other characteristics, enabling it to respond discriminatively over a stimulus intensity range of about ten billion to one. At one time, it was felt that the bleaching of photopigments was primarily involved in this process; recent evidence indicates that this plays only a minor role and the true mechanisms are numerous and include changes in the organizational properties of retinal networks.

VITREOUS STATE

The vitreous state, or the glassy state, is a special metastable condition in which a substance can exist. A material in the vitreous state may be termed a noncrystalline solid or a rigid liquid. The attainment of the vitreous state is illustrated by the volume-temperature relationship of an ideal system in Fig. 1. When a liquid is cooled slowly, crystallization will usually occur when the temperature reaches the melting point T_m as described by the path a-b. In the case of a complex liquid, crystallization will similarly commence when the temperature reaches the liquidus. Crystallization is generally considered to take place by a two-step mechanism, namely, nucleation and then crystal growth. In the absence of crystallization, a liquid can be supercooled below T_m , and the cooling path is now described by a-c. Since the fluidity of a liquid generally exhibits an exponential dependence on temperature, progressive undercooling along a-c will be accompanied by a rapid increase of viscosity. If crystallization has still not occurred when point d is reached, the viscosity of the liquid will have reached 10^{14} poises. (By comparison, the viscosity of glycerol at room temperature is only 10 poises.) For a particular cooling rate, say 5 deg/min, the cooling curve will now follow d-e. At any temperature below that corresponding to the point d, the material is said to be in the vitreous state. It now has the rigidity of the corresponding crystalline solid, but its structure is still devoid of long-range order similar to that of the parent liquid. A substance in the vitreous state is called a glass.

At the point d, the viscosity of the supercooled liquid is 10^{14} poises. At such high viscosity, molecular motions are retarded since the re-

laxation times are of the order of minutes and hours. The time taken for experimental measurements may now be actually less than the time needed to attain internal equilibrium. Thus for a particular cooling rate, an inflection will occur at d. For a slower cooling rate, d-e will be displaced to the first dashed line below it. For an even slower cooling rate, the inflection will occur at point f; the cooling curve will now be described by the lowest dashed curve. Similar behavior is shown by the heat content-temperature relationship of the system. The inflection points d and f, and hence the specific volume of a glass at the lower temperatures, are dependent on the cooling rate. The temperature region over which this inflection occurs is termed the glass-transition temperature T_g . Although the supercooled liquid at above T_g is metastable with respect to the crystalline phase, it is in internal thermodynamic equilibrium. A glass, however, is generally considered not to be in internal thermodynamic equilibrium.¹

Many substances are easily rendered into the vitreous state by supercooling the melt. These include organic liquids such as toluene and the alcohols, polymeric materials, fused salts of the system $\text{Ca}(\text{NO}_3)_2$ KNO_3 and many silicates, borates, phosphates and their mixtures.² In general the ease of glass formation via the liquid is dependent on the crystallization kinetic constants as well as the cooling rate. Although the crystallization kinetic constants of metallic systems, for instance, are not favorable for glass formation, the vitreous state is attainable by very rapid cooling. The condensation of vapor at low temperatures can also yield noncrystalline solid phases. Little is known about the relationship between such phases and the more common glassy phase obtained from the cooling of the

FIG. 1. Volume-temperature relationship of an ideal glass-forming system.

melt. Present theoretical interests are centered on the nature of the glass transition at T_g . Two important questions are: (a) Is the glass-transition region an iso-free volume state for all substances? (b) Is there a theoretical lower temperature limit to T_g ? No unambiguous answers to these questions are presently available.

WAVE MECHANICS

Introduction. It has been known since the early part of the present century that systems of atomic dimensions do not obey the laws of classical mechanics, as formulated by Newton. A new mechanics has had to be constructed, and this is called *quantum mechanics*.

There were initially two apparently different formulations of quantum mechanics, one called **MATRIX MECHANICS** and the other *wave mechanics*. It was ultimately shown that the two formulations are completely equivalent and complicated quantum mechanical problems are nowadays usually solved by a combination of both. However, there are still many applications of quantum mechanics which can be treated by purely wave mechanical methods, and as these generally make a more direct appeal to physical intuition, it is perhaps worth while to give an account of wave mechanics quite separate from matrix mechanics.*

Waves and Particles. The work of Planck, in 1900, on thermal radiation, and of Einstein, in 1905, on the photoelectric effect, suggested that light must, for some purposes, be regarded as consisting of particles, called *light quanta* or *photons*. The energy of a photon is given by

$$E = h\nu \quad (1)$$

and its momentum by

$$p = h/\lambda \quad (2)$$

where ν is the frequency and λ the wavelength of the light, and h is Planck's constant, which has the value 6.624×10^{-27} erg sec. On the other hand, diffraction phenomena, for example, can only be explained on the assumption that light consists of waves, so that neither the corpuscular nor the wave theory is completely satisfactory. In fact, it must simply be accepted that light can behave *either* as particles *or* as waves. The nature of a given experiment will emphasize one aspect or the other, and the relations between the two aspects are given by Eq. (1) and (2).

In 1924, de Broglie went further and suggested that *any* moving particle, with mass m and

speed v , will in some experiments display wave-like properties, the wavelength being given by Eq. (2), with $p = mv$. This purely theoretical suggestion received experimental confirmation in 1927, when Davisson and Germer observed the diffraction of a beam of electrons by a crystal of nickel, and similar results have since been obtained with beams of other kinds of particles, including atoms and molecules.

De Broglie's theory was the beginning of wave mechanics, but its further development was due to Schrödinger, who showed, in 1926, how the theory could be used to account for the existence of stationary states of atoms.

In 1911, Rutherford had proposed that an atom consists of a small nucleus surrounded by a planetary system of electrons. The electrons are continually accelerated; hence, according to classical electromagnetic theory, there should be a continual emission of radiation, accompanied by a diminution in the size of the electronic orbits and consequent increase in frequency. The existence of line spectra, that is, the emission of radiation in a discrete series of frequencies, and indeed the stability of matter itself, proves that this is not the case, and in 1913 Bohr suggested that an atom can exist in any one of a set of so-called *stationary states*, each with a definite energy, and with a finite energy difference between one and the next. Radiation is emitted only when an atom passes from a stationary state with energy E_1 to a state of lower energy E_2 , and the frequency ν of the radiation is given by

$$h\nu = E_1 - E_2 \quad (3)$$

Bohr attempted to graft this idea on to the classical picture of electrons describing planetary orbits about the nucleus by postulating that only certain orbits were permissible. This theory successfully explained the line spectrum of hydrogen and had several other partial successes, but it was soon superseded by the more revolutionary but also more versatile quantum mechanics.

The Schrödinger Equation. According to de Broglie's theory a freely moving particle should be represented by a wave of the form

$$\Psi(x, t) = A \exp \left[2\pi i \left(\frac{x}{\lambda} - \nu t \right) \right]$$

* According to a recent work of Dirac, the validity of wave mechanics does not extend to quantum field theory, but it remains perfectly adequate in the domain of atomic and molecular physics.

where A is a constant. Using Eq. (1) and (2), this becomes

$$\Psi(x, t) = A \exp[i(px - Et)/\hbar] \\ \psi(x) \exp(-iEt/\hbar) \quad (4)$$

where $\hbar = h/2\pi$ and

$$\psi(x) = A \exp(ipx/\hbar) \quad (5)$$

is the time-independent part of the wave (we shall deal with the time-dependent factor later).

Differentiation shows that

$$\frac{d^2\psi}{dx^2} = -\frac{p^2}{\hbar^2}\psi \quad (6)$$

However, the energy of the particle is

$$E = \frac{p^2}{2m} + V$$

the first term on the right-hand side being the kinetic energy and the second term, the potential energy, which is constant if the particle is moving under no forces. Equation (6) thus becomes

$$\frac{d^2\psi}{dx^2} + \frac{2m}{\hbar^2}(E - V)\psi = 0 \quad (7)$$

Although this equation has been plausibly derived only for a free particle, Schrödinger assumed that it also applies to a particle moving under a force, so that the potential energy V is a function of x . It is known as the *Schrödinger equation* or the *wave equation* for a particle moving in one dimension, and the function $\psi(x)$ is called the *wave function*. We will consider the interpretation of ψ below, but meanwhile let us note that ψ is to be *single-valued, continuous, smooth* [except at infinities of $V(x)$] and *finite everywhere*. Also, although $\psi \neq 0$ is always a solution of Eq. (7), it is not permitted as a wave function.

Particle in a One-dimensional Box. That the Schrödinger equation does lead to discrete energy values, at least when classical mechanics would predict a limited range of motion or a *bound* particle, can easily be seen by considering a particle moving in one dimension between infinite potential barriers—this is known as a one-dimensional box.

Suppose that the potential energy is zero from $x = 0$ to $x = L$, and infinite everywhere else. In the region of zero potential energy, Eq. (7) becomes

$$\frac{d^2\psi}{dx^2} + \frac{2mE}{\hbar^2}\psi = 0 \quad (8)$$

with the general solution

$$\psi = A \cos \sqrt{\frac{2mE}{\hbar^2}} x + B \sin \sqrt{\frac{2mE}{\hbar^2}} x \quad (9)$$

The condition of finiteness on ψ (which we will not consider in detail) demands that it vanish in

the region of infinite potential energy, and because of the condition of continuity, we must then have $\psi(0) = \psi(L) = 0$. The only solutions in the region of zero potential energy satisfying these boundary conditions are of the form

$$\psi_n = B_n \sin \frac{n\pi x}{L}, \quad n = 1, 2, 3, \dots \quad (10)$$

corresponding to the energy values E_n given by

$$\sqrt{\frac{2mE_n}{\hbar^2}} = \frac{n\pi}{L} \\ \text{or} \quad E_n = \frac{n^2\pi^2\hbar^2}{2mL^2} \quad (11)$$

($n = 0$ gives $\psi \equiv 0$, which is not allowed).

The energy E can thus have any one of an infinite set of discrete values, corresponding to the integral values of n , but no other value. These values are called the *eigenvalues* of the Schrödinger equation or *energy levels* of the system, and the corresponding wave functions are called the *eigenfunctions* of the equation and represent the stationary states of the system.

Operators. The Hamiltonian $H(x, p)$ of the one-dimensional system we have been considering is simply the energy expressed in terms of the momentum p and coordinate x , and the *equation of energy* is

$$H(x, p) = \frac{p^2}{2m} + V(x) = E \quad (12)$$

If we formally convert this into an *operator* equation by letting

$$p \rightarrow \frac{\hbar}{i} \frac{d}{dx} \quad (13)$$

(the coordinate x becomes the operator "multiply by x ", but this is trivial), and allow both sides to operate on a function $\psi(x)$, we obtain

$$\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} + V\psi = E\psi \quad (14)$$

which, when rearranged, is seen to be the Schrödinger equation [Eq. (7)].

The representation of dynamical variables by operators is fundamental to quantum mechanics, but the choice of operators made above is not unique. It may be confirmed by differentiation that

$$\frac{\hbar}{i} \frac{d}{dx} (x\psi) = x \frac{\hbar}{i} \frac{d\psi}{dx} + \frac{\hbar}{i} \psi$$

and, using Eq. (13), this gives the operator equation

$$px - xp = \frac{\hbar}{i} \quad (15)$$

The operator on the left is called the *commutator* of p and x , and is generally written $[p, x]$. Equation (15) is the basic equation of matrix mechanics and existed before Schrödinger's

equation, p and x then being represented by MATRICES. This shows in an elementary way the close connection between wave mechanics and matrix mechanics.

Particles in Three Dimensions. Equation (13) gives the clue to the extension of Schrödinger's equation to systems of one or more particles moving in three dimensions. We first write down the Hamiltonian of the system and transform each Cartesian component of momentum into a differential operator like Eq. (13) with respect to its corresponding (canonically conjugate) coordinate. For example, for a single particle moving in three dimensions, the Hamiltonian is

$$H(x, y, z, p_x, p_y, p_z) = \frac{1}{2m}(p_x^2 + p_y^2 + p_z^2) + V(x, y, z)$$

where p_x, p_y, p_z are the Cartesian components of the momentum, and the equation of energy is

$$H(x, y, z, p_x, p_y, p_z) = E \quad (16)$$

If we transform the latter into an operator equation by writing

$$p_x = \frac{h}{i} \frac{\partial}{\partial x}, \quad p_y = \frac{h}{i} \frac{\partial}{\partial y}, \quad p_z = \frac{h}{i} \frac{\partial}{\partial z} \quad (17)$$

(partial derivatives are now required as several variables are present), and operate upon a function $\psi(x, y, z)$, we obtain the equation

$$-\frac{h^2}{2m} \left(\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} + \frac{\partial^2 \psi}{\partial z^2} \right) + V(x, y, z)\psi = E\psi \quad (18)$$

which is the Schrödinger equation of the system. The essential correctness of this equation has been amply demonstrated by many successful applications (this is, of course, the *only* justification of any of the postulates of quantum mechanics). In particular, in the case of the hydrogen atom, where there is a single electron moving under the Coulomb attraction of a single proton (which may as a good approximation be considered to be at rest), the equation can be solved analytically, and the energy levels so found, together with the Bohr frequency rule [Eq. (3)], correctly give the line spectrum of hydrogen.

The extension to many particles is straightforward; in the Hamiltonian of the system, the substitutions of Eq. (17) are made for the momentum components of each particle of the system, and the equation of energy is thus transformed into the Schrödinger equation. Again the equation has had many successful applications, an early one being the calculation of the energy of the normal helium atom by Hylleraas in 1930, which the earlier Bohr theory failed to do. Unfortunately, owing to the interaction of the electrons, the equation cannot be solved analytically for many-electron systems and resort must be made to approximate methods of solution which have become extremely complicated in recent years.

Interpretation of the Wave Function. Let us consider the Schrödinger equation for a single particle moving in three dimensions. This is a linear equation, so that if ψ is a solution, so also is $C\psi$, where C is any constant. This means that (in most cases) we can choose ψ so that

$$\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} |\psi(x, y, z)|^2 dx dy dz = 1 \quad (19)$$

The function ψ is generally complex and $|\psi|$ is its *modulus* ($|\psi|^2 = \psi^* \psi$, where ψ^* is the complex conjugate of ψ). If it satisfies Eq. (19), the function ψ is said to be *normalized*.

The interpretation of ψ demands that it be normalized. If this is not possible, owing to the divergence of the integral in Eq. (19), as is the case with a free particle, then normalization has to be affected artificially by enclosing the system in a large box.

It was proposed by Born, in 1926, that if the particle is in a stationary state, with normalized wave function ψ , then $|\psi|^2$ may be interpreted as a *probability density*, such that

$$|\psi(x, y, z)|^2 dx dy dz$$

is the *probability* of finding the particle in the small volume element $dx dy dz$ at the point (x, y, z) .

It is clear from this why normalization is necessary—Eq. (19) expresses the fact that the probability of finding the particle *somewhere* is unity.

An important extension of this interpretation, which we will not justify in detail, relates to the *average* or *expectation value* \bar{f} of a dynamical variable f (such as momentum) for a system in a state ψ , i.e., the average of a large number of measurements of f made on a system in this state. It is found that

$$\bar{f} = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \psi^* f_{op} \psi dx dy dz \quad (20)$$

where f_{op} is the quantum mechanical operator representing f . Here we have restricted ourselves to a single-particle system, but the same applies to systems of any number of particles, so long as the integral is a multiple integral taken throughout the full range of all the variables appearing in ψ .

The interpretation of ψ , or rather of $|\psi|^2$ (ψ itself has no physical significance), which we have presented above, gives rise to a fundamental and important difference between classical mechanics and quantum mechanics. According to the latter, there is a finite probability of finding a particle in regions of space where its presence would be forbidden by classical mechanics—regions where its kinetic energy would be negative.

Let us take as an example the linear harmonic oscillator. Suppose a particle of mass m is moving along the x axis under the action of a force $-kx$ (k is positive) directed towards the origin. Classically, the particle executes simple harmonic motion with frequency $\omega/2\pi$, where

$\omega = \sqrt{k/m}$. It is easy to see that the potential energy is $V(x) = \frac{1}{2}m\omega^2 x^2$, if the zero of potential energy is taken to be at $x = 0$, so that the Schrödinger equation [Eq. (7)] becomes

$$\frac{d^2\psi}{dx^2} + \frac{2m}{\hbar^2} \left(E - \frac{1}{2}m\omega^2 x^2 \right) \psi = 0 \quad (21)$$

It may be verified by substitution that the function

$$\psi_0 = \exp(-m\omega x^2/2\hbar) \quad (22)$$

satisfies this equation, provided E has the value

$$E_0 = \frac{1}{2}\hbar\omega \quad (23)$$

This is, in fact, the *ground state* of the oscillator, that is to say, E_0 is the lowest energy level.

Now, according to classical mechanics, the particle, having energy E_0 , would be confined to a region of the x axis whose limits are given by setting $V(x) = E_0$, that is, $x = \pm \sqrt{\hbar/m\omega}$. However, ψ_0 tends to zero asymptotically as x tends to $\pm \infty$, so that, according to the interpretation of $|\psi|^2$, there is a finite probability of finding the particle at very large distances from the origin. This is known as the *tunnel effect* and has an important application in the theory of radioactive decay.

The foregoing example demonstrates another point in which quantum mechanics differs from classical mechanics. According to the latter, the oscillator could have zero energy (when the particle is at rest at the origin), but this is not permitted in quantum mechanics—the *lowest* energy the oscillator can have is $\frac{1}{2}\hbar\omega$, which is called its *zero-point energy*.

Time Dependence. So far we have only considered the stationary states of a system and, furthermore, only of a *conservative* system, i.e., one whose energy is constant. However, if a system is subject to a disturbance which varies with time, for example, due to the passage of a charged particle or a light wave through it, there is a probability that the system will in a certain time make a transition from its initial stationary state to some other stationary state. In order to calculate such *transition probabilities*, it is necessary to consider explicitly the time dependence of wave functions, which we have so far neglected, and this entails the use of a modified Schrödinger equation.

Differentiation of the function $\Psi(x, t)$, Eq. (4), gives

$$E\Psi = i\hbar \frac{\partial \Psi}{\partial t} \quad (24)$$

which suggests that the energy E should in general be represented by the operator

$$E = i\hbar \frac{\partial}{\partial t} \quad (25)$$

If we convert the equation of energy [Eq. (12)] for a one-dimensional system into an operator, using Eqs. (13) and (25), and if we allow both

sides to operate upon a function $\Psi(x, t)$, we obtain

$$-\frac{\hbar^2}{2m} \frac{\partial^2 \Psi}{\partial x^2} + V\Psi = i\hbar \frac{\partial \Psi}{\partial t} \quad (26)$$

[the derivative in Eq. (13) has been replaced by a partial derivative as we now have two variables, x and t]. This is known as the *time-dependent Schrödinger equation*; it applies even when the potential energy function V depends explicitly upon the time. If more than one dimension or several particles are involved, it is only necessary to use the appropriate quantum mechanical Hamiltonian operator on the left-hand side. It should be emphasized that this equation has *not* been rigorously derived, but only plausibly suggested. No such derivation exists, either for Eq. (26) or for Eq. (7)—their justification lies entirely in their successful application.

If we are, in fact, dealing with a conservative system, so that V does not depend explicitly upon t , it is easy to verify by substitution (and indeed this is obvious from the way in which the equation was derived) that Eq. (26) has solutions of the form

$$\Psi(x, t) = \psi(x) \exp(-iEt/\hbar) \quad (27)$$

where $\psi(x)$ is an eigenfunction of Eq. (7) and E is its corresponding eigenvalue. The function $\psi(x)$ is the time-independent wave function of a stationary state, and $\Psi(x, t)$ is the time-dependent wave function. Since it is not ψ but $|\psi|^2$ which has physical significance, and Eq. (27) shows that $|\Psi|^2 = |\psi|^2$, it is clear that so long as we are dealing with the stationary states of a conservative system, the time dependence of the wave function is of no importance.

Conclusion. The foregoing account has been confined to the elementary ideas of wave mechanics, due to de Broglie and Schrödinger. No mention has been made, for example, of the relativistic wave equation, due to Dirac, or of the important concept of electron spin. Further information on wave mechanics, its applications, and its relationship with the rest of quantum mechanics can be obtained from the article on MATRIX MECHANICS in this book and from a vast number of books of which those listed in the references are a very small sample.

WAVE MOTION

Wave motion can be said to be the most common and the most important type of motion that we know. It is through wave motion that sounds come to our ears, light to our eyes, electromagnetic waves to our radios and television sets, and tidal waves and earthquakes to our cities. Wave motion can be defined as that mechanism by which energy is transported from a source to a distant receiver without the transfer of matter between the two points.

Waves can be classified according to the manner of their production, namely, a vibrating material object or, in the case of electromagnetic waves, sources such as electrical oscillations in an aerial. The wind blowing across water causes surface waves; a piezoelectric quartz crystal vibrating under an applied electric field generates underwater wave motion. Or, waves could be classified according to the medium in which they travel. The most useful classification, however, involves the direction of motion of the particles of a medium (or of an electric or magnetic field in the case of electromagnetic waves) relative to the direction in which the energy of the wave is itself propagated. Such a classification is useful because wave motions falling into the same class according to the selected criterion will have other similar properties.

Wave motion can be most easily understood if one considers first, as an example, wave motion in a horizontal, stretched string and then, by analogy, other types of wave motion. If one end of such a string is moved up and down, a rhythmic disturbance travels along the string. Each particle of the string moves up and down, while, at the same time, the wave motion moves along the length of the string. It is the state of the particles that advances, the medium as a whole returning to its initial condition after the disturbance has passed. Such a wave motion, one in which the vibratory motion of the medium is at right angles, or essentially at right angles, to the direction of propagation, is called transverse. Surface waves on liquids are transverse; so also are electromagnetic waves (x-rays, visible light, radio waves, and so forth), but here, since electromagnetic waves can travel in a vacuum, we must think of the electric and magnetic fields associated with such waves as changing in intensity in a direction at right angles to the direction of propagation.

Another type of wave motion, one termed longitudinal or compressional, can occur only in material media and has the particles of the medium moving forward and backward along the direction of propagation of the wave. Compressional waves are exemplified by sound waves in air, in which a volume in the path of the wave is alternately compressed and rarefied. These variations in pressure are very small. Even for the loudest sounds that an ear can tolerate, the pressure variations are of the order of 280 dyne/cm^2 (above and below atmospheric pressure of about $1\,000\,000 \text{ dyne/cm}^2$).

Yet another type of wave motion is the torsional wave, which can take place only in solids. Less frequently seen, this type can be demonstrated by a long helical spring supported on a flat surface. As one end of the spring is given a quick, momentary twist about the axis of the spring, a pulse travels down the spring.

Whatever the type of wave, certain useful definitions can be set forth and general statements made. Phase describes the relative position and direction of movement of a particle in its periodic motion as it participates in wave motion, of the relative intensity at a point of the electric field accompanying electromagnetic waves. Frequency is the number of complete vibrations performed per unit of time by a particle (or field) through which a wave passes. Period is the time required for one complete vibration of a particle participating in wave motion. Wavelength is the distance between any two points that are in phase on successive waves or pulses. The velocity of a wave is the product of the frequency and the wavelength. All waves except electromagnetic waves require a medium for their propagation.

Wave motions may vary in the energy they transport per unit of time. This property depends on the amplitude. The amplitude of a wave in a string, to take again an example, is the maximum displacement experienced by the particles of the string as they move from their equilibrium positions. The intensity of the wave is the power (energy per second) passing through a square centimeter perpendicular to the wave front, and it is related to the square of the amplitude. In the case of sound, intensity is related to loudness.

Two or more waves crossing one another's paths will not cause any change in the direction, frequency, or intensity of any of them. The displacement effects of two or more waves of the same kind passing through a medium are additive at any point; and at any moment, the displacement at a point is the vector sum of the separate displacements caused by the separate waves. Two transverse wave motions passing at right angles through a point in a medium cause a particle at that point to perform a path called a Lissajous figure, whose form depends upon the amplitudes and frequencies of the two waves and upon their phase relationship.

Wave motion also experiences the phenomena of absorption, reflection, refraction, interference, diffraction, beats, resonance, and polarization. However, longitudinal waves do not exhibit the property of polarization.

Complex waves can be analyzed into sets of simple waves according to the principles of Fourier analysis, where by "simple waves" are meant waves whose variations of displacement with time can be represented by sine curves.

Compressional waves require about 5 seconds to travel a mile in air, 1 second to travel a mile in water, and $1/3$ second to travel a mile in iron. Though varying in speed from material to material, low-frequency compressional waves travel with the same speed in a particular medium, i.e., they do not exhibit dispersion. Small

variations in speed sometimes found at high frequencies are due to relaxation phenomena.

Compressional waves in a fluid have a speed v that depends only on the density ρ and the adiabatic bulk modulus β of the medium according to the relation

$$v = \sqrt{\frac{\beta}{\rho}}$$

In solids, the speed of compressional waves is given by the relation

$$v = \sqrt{\frac{Y}{\rho}}$$

where Y is Young's Modulus. Thus it may be seen that a study of the propagation of waves in a medium gives important information about the medium.

Transverse waves on the surfaces of liquids do not travel with a fixed speed dependent only on the properties of the liquid. Their speed depends upon their wavelength and amplitude, the depth of the liquid, and whether the surface is confined, as in a canal. Surface tension waves on the surface of water have wavelengths less than 1.7 cm, while gravity waves on the surface of water have wavelengths greater than 1.7 cm. Ripples on water often move only 1 ft/sec. They have higher velocity as their wavelength becomes smaller. In contrast, for example, ocean waves measuring 800 feet from crest to crest have been found to travel 45 mph.

Transverse waves in strings (or wires) travel with a speed that depends only on the tension in the string T and the mass per unit length of the string m , according to the formula

$$v = \sqrt{T/m}$$

Electromagnetic waves of all frequencies travel with the same speed in a vacuum (2.9979×10^{10} cm/sec). In a particular medium, however, different frequencies (colors in the case of visible light) travel with different speeds. The speeds at particular frequencies also vary with the media.

The observed wavelength of a wave motion, whether it be longitudinal or transverse, depends on whether the source and the receiver are moving relative to one another, a phenomenon known as the Doppler effect. In the case of electromagnetic waves, the Doppler effect depends only on the relative velocity; in the case of a compressional wave, as for instance, sound, the magnitude of the effect depends not only on the relative velocity of the source and receiver but upon which is in motion with respect to the transmitting medium. In both cases the wavelength of the wave is increased if the source and receiver move away from one another and decreased if they move toward one another.

In some uses of wave motion, care must be taken to differentiate between "phase" and "group" velocity. The group velocity of a wave is usually the observed velocity, and the energy in a wave is transmitted with the group

velocity. The phase velocity refers to the speed of a point of fixed phase in the wave, as, for example, a crest in a water wave.

WAVEGUIDES

Fundamental Principles. A waveguide is a hollow pipe used as a transmission line. Its cross section is usually rectangular, square, or round, but irregular shapes are sometimes used for special applications. The electromagnetic wave in the waveguide can have an infinite variety of patterns, called modes, and, in general, these modes are of two kinds. In one set of modes, the electric vector is always transverse to the direction of propagation; in the other set, the magnetic vector is always transverse to this direction. The former are called TE or *transverse electric* modes, the latter are TM or *transverse magnetic*. Two subscripts are used to designate a particular mode. The first subscript (in either kind of mode) designates the number of half-wave variations of the electric field across the wide dimension of the waveguide, and the second designates the number of half-wave variations of the electric field across the narrower dimension. Thus, a $TE_{2,1}$ mode would designate a field pattern in which the electric field is always transverse to the propagation direction and in which the electric field has two half-wave variations across the wide dimension and one across the narrow.

For each mode of operation there is a cutoff wavelength, determined by the size and shape of the waveguide. For the $TE_{1,0}$ mode in a rectangular waveguide, the cutoff wavelength is twice the wide dimension. This means that when the signal wavelength is less than cutoff, the energy will propagate in the waveguide; but, when it is greater, the energy is attenuated exponentially. In the latter case, the frequency is too low to propagate through the waveguide and is said to be "below cutoff." Cutoff for other modes in rectangular guides is higher than for the $TE_{1,0}$. Consequently, for any frequency it is possible to choose dimensions so that only the $TE_{1,0}$ mode is above cutoff, and all other modes will be rapidly attenuated. The $TE_{1,0}$ mode is called the *dominant mode* and is the one most commonly used.

The attenuation through a waveguide is a function of the material of which it is fabricated. With suitable materials, the waveguide will have less attenuation at a particular frequency than a coaxial line of the same size. The losses in the waveguide are copper losses in the walls, and consequently the walls should be made of a

highly conducting material. At microwave frequencies the skin depth is only a few thousandths of an inch. Therefore, it is common practice to make the waveguide out of an inexpensive material such as brass, or a lightweight material, such as aluminum, and then to plate it with silver or copper for good conductivity. For prevention of oxidation, the conducting layer may be plated with a thin coating of rhodium. However, since rhodium has a higher resistivity than silver, this coating must be thinner than the skin depth of rhodium so that the current flows mainly in the silver layer.

Brass is the most common metal for waveguides because it is easily machined and easily soldered. For airborne applications where weight is a consideration, aluminum or magnesium is preferred. At very high frequencies, above 40 kMc, silver is frequently used, since the amount of metal used is small and costs less than the cost of a brass guide, silver plated.

Besides the simpler construction and lower loss, waveguides have higher power carrying capacity than coaxial cables. The waveguide is a completely shielded transmission line and may be bent and twisted with no radiation loss. However, whenever the waveguide is made to change direction, care must be taken to keep the cross section uniform or there will be a reflection from the discontinuity.

All discontinuities in waveguides are equivalent to lumped-circuit elements in conventional transmission lines. A screw inserted in the broad wall or a dent in this wall is a shunt capacity. A post across the waveguide is a shunt inductance. An iris across the waveguide with its edges parallel to the voltage vector is a shunt inductance. If its edges are parallel to the magnetic vector, the iris is a shunt capacity. A change in dimensions of the waveguide is a change in characteristic impedance, and a quarter-wave length of guide with new dimension is thus a quarter-wave transformer. All of these elements are used to match out the effects of more complicated mismatches.

In matching impedances or making quarter-wave transformers, the wavelength used is not the wavelength in free space, for the wave travels in the waveguide at a velocity apparently greater than that of light. Actually, this is the *phase velocity* of the wave and is the apparent speed of an unmodulated wave. The signal or modulation on the wave travels at a speed less than that of light called the *group velocity*. The product of the group velocity and the phase velocity is equal to the square of the speed of light. The phase velocity divided by the frequency is equal to the quantity called the *guide wavelength*, which is used for all matching calculations.

Waveguide Components. Two pieces of waveguide or two waveguide components may be joined together by means of flanges soldered on the ends of the guides. Flanges are of two types: (1) *cover flanges*, which are flat plane surfaces, and (2) *choke flanges*, which have a quarter-wave deep groove cut in them. This groove is also a

quarter-wave from the waveguide wall. The choke presents a short-circuit impedance between the two pieces of guide even if they are separated slightly or misaligned. It is thus possible to have a microwave coupling which is a short at radio frequency and an open circuit at direct current. By using a quarter-wave transformer, the reverse is also possible.

A choke joint is also used in a rotary or motional joint, where it is desired to move one waveguide with respect to another and at the same time to maintain electrical continuity. This goal is accomplished by physically separating the two pieces and using the choke to present an electrical short circuit at the microwave frequency.

In the rotary joint and in other microwave circuits, it is necessary to change from one form of waveguide to another or from waveguide to coaxial line. The problem in designing such adapters is basically one of matching impedances over a required frequency range. Coaxial line-to-waveguide adapters have been built with a voltage standing-wave ratio (VSWR) of 1.10 or better over a 30 per cent frequency band. Adapters from the dominant mode ($TE_{1,0}$) in rectangular guide to the dominant mode ($TE_{1,1}$) in round guide have been built with a VSWR of 1.05 over the same frequency range. In both cases the rectangular guide may be either perpendicular to, or in line with, the other transmission line.

The VSWR is measured by means of a *slotted line*. This is a section of waveguide, identical to that being tested, with a thin slot in the center of one broad wall, parallel to the direction of propagation. A probe is lightly coupled through the slot, and as it is moved along the slot, voltage maxima may be determined. This information can be used to calculate the impedance of the piece being tested.

In making the impedance measurements, the piece being tested must be properly terminated. That is, in order to measure only the discontinuity at the face of the slotted line, there must be no other discontinuities reflecting energy back to this point. The termination or *matched load* is usually a piece of waveguide containing an absorbent material which has been tapered to a point in the direction from which the energy is coming. Absorbent materials frequently used are resistance cards, carbon, plastics loaded with metal particles, sand, and wood. For very accurate measurements, the load material may be slid along the guide to determine whether it is properly matched. If a load is perfect, there will be no voltage variations observed at the slotted line probe as the load is moved in the guide.

A tee is a component consisting of a straight piece of waveguide with another piece fastened to it at right angles. The junction is open so that energy fed into any arm sees two possible paths at the junction. When the auxiliary arm is fastened to the broad wall of the main waveguide, the voltage or *E* vector in the side arm is perpendicular to the *E* vector in the main guide. Such a tee is called an *E-plane tee*. When properly matched, energy fed into the *E*-arm will divide

equally in the other two arms but 180° out of phase. This tee is also called a *series junction tee*. When the auxiliary arm is fastened to the narrow wall of the main waveguide, the magnetic or H vector in the side arm is perpendicular to the H vector in the main guide. This is an *H-plane tee* or *shunt junction tee*. When properly matched, energy fed into the H -arm will divide equally and in phase in the other two arms.

When the component has both an E-arm and an H-arm at the same point in the main line, it is called a *hybrid tee*. (The two main line terminals are now called side arms.) When properly matched, the tee has special properties and is called a *magic tee*. In this tee, energy fed into the E-arm or the H-arm divides equally in the other two arms and there is no coupling between the E- and H-arms. Energy fed into one side arm divides equally between the E and H arms, and there is no coupling to the other side arm.

When energy is fed into both side arms, the algebraic sum of the signal intensities appears at the H-arm, and the difference appears at the E-arm.

When two waveguides are joined together by two or more coupling paths, it is possible to choose dimensions such that energy in the first guide will be coupled a predetermined amount to the second and will travel in only one direction in the second guide. Then the output at one terminal in the second guide will be a measure of the power flowing in one direction only in the first guide. This component is called a *directional coupler*.

A piece of waveguide with two large discontinuities will have strong reflections between them. If the two discontinuities are spaced a multiple of half wavelengths apart, the reflections will reinforce each other and the section will be *resonant*. A resonant section or cavity is analogous to a fixed tuned circuit at lower frequencies. If the spacing of the discontinuities is adjustable, it is a variable tuned circuit. Since the frequency or resonance depends on the spacing, resonant cavities are used as wavemeters. The storage factor Q of the cavity depends upon the conductivity of the walls, the shape, the magnitude of the discontinuities, and the lightness of coupling. With silver plated walls and short-circuits, Q 's above 5000 have been obtained.

Attenuators and phase shifters are made by moving a piece of material into the waveguide so that it couples with the electric field. The motion can be calibrated and related to the amount of attenuation or phase shift. If the material is lossy, the component is an attenuator. If the material has low loss, but a dielectric constant more than unity, the velocity of propagation through it will be different from that in the empty guide, and phase shift results.

GERSHON J. WHEELER

WEAK INTERACTIONS

The weak interactions present a fascinating aspect of the problem of elementary particles. They appear at first to be totally unrelated to the other interactions that we know, nonetheless there have been discovered striking regularities among them, which can only be described in terms of symmetries which were originally ascribed to strong interactions alone. Without attempting to describe these, for which we must refer the reader to one of the books listed at the end of this article, we present here a brief history of the subject, which has been marked by many surprises.

To avoid the difficulties found in understanding processes of β -decay (see RADIOACTIVITY), in 1931, Pauli suggested that the emission of a β -particle from a nucleus is always accompanied by that of a spin-1/2 neutral particle of small mass, which takes account of energy and angular momentum conservation in β -decay. Calorimetric measurements of the average energy release in a β -decay transition agree quite well with the value calculated from direct measurement of the β -decay spectrum, indicating that the hypothetical particles, which were called neutrinos, must interact extremely weakly with matter, since they escape from the apparatus without giving up any measurable energy. A quantitative theory of β -decay, incorporating the NEUTRINO hypothesis was formulated in 1934 by Fermi, who wrote down the simplest relativistic expressions which would describe the basic β -transition: the transformation of a neutron into a proton accompanied by the creation of an electron and a neutrino. This theory has been strikingly successful in describing all aspects of β -decay—with one qualification to be described later—and is the one employed to this day. It could be anticipated from the weakness of the neutrino's interaction with matter that the coupling constant characteristic of β -decay would be small; it is in fact extremely small.* Adopting a simile of Lord Rutherford, one may say that from the point of view of the nucleus, β -decay practically never happens! To judge the scale, we note that lifetimes for β -decay are commonly several minutes whereas γ -transitions of similar energy occur in nanoseconds or less.

The success of Fermi's theory in accounting for the shapes of β -spectra and the dependence of the lifetimes on the available energy release could be regarded as indirect evidence for the existence of the neutrino; there were also other indications such as the occurrence of the predicted nuclear recoil after processes of orbital electron capture, a phenomenon predicted by the theory. Nonetheless, there was considerable satisfaction when the existence of the neutrino was directly demonstrated by Cowan and Reines in 1955 (for Reines' discussion see NEUTRINO). They used

Cross-references: CAPACITANCE, DIELECTRIC THEORY, INDUCTANCE, MICROWAVE TRANSMISSION, PROPAGATION OF ELECTROMAGNETIC WAVES.

* An average β -decay neutrino must pass through a thickness of matter of the order of 10^{20} g/cm² before suffering an interaction.

the intense neutrino flux arising from free neutron decays near a reactor to induce inverse β -decay, i.e., the conversion of a proton into a neutron with the emission of a positron, at roughly the expected rate. A similar experiment by Davis gave a negative result. In Davis' case, however, the reaction sought was the inverse of a β^+ -decay transition although the neutrinos available to him were the same as those used by Cowan and Reines, i.e., neutrinos arising from the β^- -decay of neutrons. The non-occurrence of the Davis reactions demonstrates that the neutrinos emitted in β^- -decay must be physically distinct from the neutrinos associated with β^+ -decay. This conclusion is supported by the absence of neutrinoless double β -decay, a process in which the neutrino from the β -decay of one nucleon could be reabsorbed within the same nucleus to induce the β -transition of a second nucleon.

Universal Fermi Interaction. The μ -mesons, or muons, (see ELEMENTARY PARTICLES) which were originally identified with Yukawa's mesons, were found to interact only very weakly with matter. In fact, it was noted that their absorption could be regarded as a process exactly similar to orbital electron capture, i.e., by an interaction just like that of β -decay, with even the same coupling constant! The decay of a muon, into an electron and two neutral particles, presumably neutrinos, was also accounted for by assuming a Fermi coupling of these four particles, again with a coupling constant of the same magnitude. This led to the hypothesis of a Universal Fermi Interaction between fermions, and after the discovery of "strange" particles (see STRONG INTERACTIONS), the natural extension of this hypothesis to include hyperons led to a qualitative understanding of all strange particle decays.*

The Universal Fermi Interaction does not, however, act between any set of four fermions. Interactions involving an electron or a muon always include a neutrino; furthermore, simple selection rules are found to operate for the weak interactions of strongly interacting particles. On the other hand, detailed experiments have revealed that the form of the Fermi Interaction is that of a current-current coupling, just as the electro-magnetic interaction of two systems may be regarded as the interaction between their currents. It has therefore been suggested that the Fermi interaction may arise as a result of the interaction between currents which generate a vector field similar to the electromagnetic field which mediates the weak interaction. To account for the short range of the Fermi interaction, the quanta of this field must be very massive, which may account for the fact that these particles have not been seen so far. The selection rules for weak interactions could be understood by assigning suitable properties to this field.

* The β -decay of hyperons occurs an order of magnitude more weakly than nuclear β -decay. To account for this in terms of an Universal Fermi Interaction, one must modify the definition of universality.

Fermi's theory predicts that the cross section for neutrino interactions increases quadratically with neutrino energy. This growth is not expected to continue after the neutrino wavelength becomes smaller than nucleon dimensions, but the cross section at the corresponding energy, about 1 GeV, is already sufficient for experiments using the high-energy neutrino beams from the decays of fast π - and K -mesons produced by high-energy accelerators. One of the first results of such experiments has been to demonstrate the striking fact that the neutrino associated with muon capture, which is the one predominantly produced in meson decays, is unable to produce electrons, proving that it is physically distinct from the neutrino of β -decay. High energy neutrino experiments can give us much more information about the structure of weak interactions than the limited number of decay processes which are available for study.

An aspect of weak interactions which we have not mentioned thus far, is that they possess fewer space-time symmetries than the strong interactions. Until Lee and Yang pointed out the possibility in 1956, it was not suspected that any interaction could distinguish between left-handed and right-handed coordinate systems.

It was then found that weak interactions discriminate between them very strongly; the question of how one system could be preferred over the other, was answered by Landau's principle of combined inversion. The apparent spatial asymmetry in a given experiment, is predicted to be exactly the mirror image of that to be expected in an experiment performed with the corresponding antiparticles; this prediction has been verified in several experiments. Fermi's theory, modified to allow for the nonconservation of parity, accounts almost perfectly for all weak interactions for which quantitative predictions can be made. A recent experiment,³ however, indicates a violation of the principle of invariance under combined inversion. Should this be upheld, it will demonstrate that weak interactions have more surprises in store.

WORK, POWER AND ENERGY

In the strict physical sense, work is performed only when a force is exerted on a body while the body moves at the same time in such a way that the force has a component in the direction of motion. The amount of work done during motion from point "a" to point "b" can be expressed by:

$$W = \int_a^b F \cos \theta \, ds$$

where F is the total force exerted and θ is the angle between the direction of F and the direction of the elemental displacement ds . In the cgs system the unit of work is the dyne-centimeter or erg, in the mks system the newton-meter or joule, and in the English system the unit of work is the foot-pound.

In rotational motion, the definition just given can be exactly applied, but it is often convenient to express the force as a torque and the motion as an angular displacement. The work done will be:

$$W = \int_a^b \tau \cos \theta \, d\omega$$

where in this case θ is always the angle between the torque τ expressed as a vector quantity and the elemental angular motion $d\omega$, also expressed as a vector. The units of work performed in angular motion will, of course, be the same as in the case of linear motion. Notice that the definition of work involves no time element.

Power is defined as the rate at which work is performed. The average power accomplished by an agent during a given period of time is equal to the total work performed by the agent during the period, divided by the length of the time interval. The instantaneous power can be expressed simply as

$$P = \frac{dW}{dt}$$

In the cgs system, power has the units of ergs per second; in the mks system, units of joules per second (or watts), and in the English system, units of foot-pounds per second. A common engineering unit is the horsepower, defined as 550 foot-pounds per second, or 33 000 foot-pounds per minute.

Energy may be defined as the capacity for performing work. This definition may be better understood when stated as: the energy is that which diminishes when work is done by an amount equal to the work so done. The units of energy are identical with the units of work, previously given.

Energy can exist in a variety of forms, some more recognizable as being capable of performing work than others. Forms in which the energy is not dependent upon mechanical motion are generally referred to as forms of potential energy. The most common example in this category is gravitational potential energy. A body near the earth's surface undergoes a change in potential energy when it is changed in elevation,

the amount being equal to the product of the weight of the body and the change in elevation.

Potential energy may also be stored in an elastic body such as a spring or a container of compressed gas. It may exist in the form of chemical potential energy, as measured by the amount of energy made available when given substances react chemically. Potential energy also exists in the nuclei of atoms and can be released by certain nuclear rearrangements.

Kinetic energy is the energy associated with mechanical motion of bodies. It is quantitatively equal to $\frac{1}{2}mv^2$ where m is the mass of a body moving with velocity v . In the case of rotational motion, the kinetic energy is more easily calculated using the expression $\frac{1}{2}I\omega^2$, where I is the moment of inertia of the body about its axis of rotation and ω is the angular velocity. Kinetic energy, like all forms of energy, is a scalar quantity. In a system made up of an assembly of particles, such as a given volume of gas, the total kinetic energy is equal to the sum of the kinetic energies of all the molecules contained in the volume. Calculation of the energy of such systems is very successfully treated theoretically on the basis of statistical averages.

Within a given system, energy may be transformed back and forth from one form to another, without changing the total energy in the system. A simple example is the pendulum, in which the energy is periodically converted from gravitational potential energy to kinetic energy and then back to gravitational potential energy. A similar situation, but on a submicroscopic scale, occurs in solid materials where the atoms are vibrating under the effect of interatomic rather than gravitational forces. As the temperature of a solid increases, the energy associated with the vibration of the atoms increases.

The example just given illustrates how, on a macroscopic scale, heat can be considered a form of energy. Regardless of the material involved, any amount of heat absorbed or released may be quantitatively expressed as an amount of energy. A gram-calorie of heat is equivalent to 4.19 joules, and in the English system a British thermal unit (Btu) is equivalent to 778 foot-pounds.

Potential energy is also present in electric and magnetic fields. The energy available in a region of electric field is equal to $E^2/8\pi$ per unit volume, where E is the electric field strength. Within a given volume, the total energy represented by the electric field is the integral of $E^2/8\pi$ over the volume. Similarly, the energy represented by a magnetic field may be independently calculated by integrating $H^2/8\pi$ over any given volume, where H represents the magnetic field strength. In the case of an electrically charged capacitor, the total energy in the electric field, and hence in the capacitor, can be shown to be $\frac{1}{2}CV^2$. Here C is the capacitance and V the electric potential to which the capacitor is charged. Similarly the total energy in the magnetic field associated with an inductor carrying an electric current is $\frac{1}{2}LI^2$, where L is the inductance and I the current.

Electromagnetic radiation is a combination of rapidly alternating electric and magnetic fields. Energy is associated with these fields and is exchanged between the electric and magnetic forms. This energy in a quantum of electromagnetic radiation, such as light or gamma radiation, can be represented in different ways, but is commonly expressed as $E = h\nu$. Here h is Planck's Constant and ν is the frequency of the radiation.

For particulate radiation or any very rapidly moving mass, the expression previously given for the kinetic energy, $\frac{1}{2}mv^2$, is not accurate when the velocity approaches that of the velocity of light. The theory of relativity requires a correction be made, and the exact kinetic energy, T , may be calculated in terms of the mass, m , of the body measured when at rest, and the speed of light in vacuum, c , as follows:

$$T = mc^2 \left[\left(1 - \frac{v^2}{c^2} \right)^{-\frac{1}{2}} - 1 \right]$$

Notice that this formula may also be written:

$$T = (m - m_0)c^2$$

where m is the variable quantity $m_0 \left(1 - \frac{v^2}{c^2} \right)^{-\frac{1}{2}}$.

This quantity represents the mass of the body, reducing to m_0 when v is zero, and approaching infinity as v approaches the speed of light.

This example illustrates another result of the theory of relativity, namely, the equivalence of mass and energy. Rewriting the last equation,

$$m = m_0 + \frac{T}{c^2}$$

The mass is seen to increase linearly with the kinetic energy of the body, the proportionality factor being c^{-2} . Indeed, even the rest mass, m_0 , represents an amount of energy equal to m_0c^2 . The total energy of a body of mass, m , can be generally given as:

$$E = mc^2 \text{ or } E = m_0c^2 + T$$

In dealing with radiation, whether particulate or electromagnetic, it is customary to express

energy in terms of electron volts. An electron volt is equal to the amount of work done when an electron moves through an electric field produced by a potential difference of one volt. One electron volt is equivalent to 1.60×10^{-12} erg. When charged particles such as electrons or protons are given kinetic energy by an accelerator, their kinetic energy is stated in terms of electron volts (eV) or million electron volts (MeV). In addition, any such particle will have a rest mass which can also be specified as an energy. For an electron,

$$m_0 = 9.11 \times 10^{-28} \text{ gram}$$

which is equivalent to 8.18×10^{-7} erg or 0.515 MeV.

A basic principle of physics is known as conservation of energy. This principle requires that within any closed system, the total energy must remain a constant. Energy can be changed from one form to another; but the total, so long as no energy is added to or lost from the system, must be constant. In the case of the swinging pendulum decreases in kinetic energy reappear as increases in potential energy and vice versa. Eventually, of course, the pendulum will stop due to the effect of frictional forces. At that time, all of the kinetic and gravitational potential energy will have been converted to heat.

In another example involving a radioactive atom, the total energy represented by the atom and the emitted radiation must be constant. If a gamma ray is emitted, the rest mass of the atom will be decreased by an amount equivalent to the sum of the energy of the gamma ray and the recoil kinetic energy of the atom, which will be very small. If a beta ray is emitted, the rest mass of the atom will be decreased by an amount equivalent to the sum of the rest mass of the emitted electron, the kinetic energy of the electron, and the recoil kinetic energy of the atom.

X

X-RAY DIFFRACTION

X-rays are electromagnetic radiations, and like visible light, they can be diffracted (see OPTICS, PHYSICAL and DIFFRACTION). If a diffraction grating is used, the situation is as shown in Fig. 1. The points B, B', B'', ... along OX represent the lines of the grating seen end-on, and ABC, A'B'C', ... are typical incident and scattered

FIG. 1. Diffraction by a linear grating or line of scattering centres.

rays of a parallel incident beam. If D' is the foot of the perpendicular dropped from B on to A'B' and D is the foot of the perpendicular from B' to BC, the extra distance traveled by the ray A'B'C' is clearly D'B' - DB. This path difference can be expressed in terms of the grating space a , the angle of incidence ϕ_1 , and the angle of scattering ϕ_2 . From the triangle BB'D', D'B' = $a \cos \phi_1$, and from the triangle BB'D, DB = $a \cos \phi_2$. If there is to be appreciable intensity diffracted in the direction BC, the path difference must be an integral multiple of the wavelength λ , say $h\lambda$. Then

$$h\lambda = a(\cos \phi_1 + \cos \phi_2) \quad (1)$$

In order to obtain any appreciable scattering of x-rays from a grating it is necessary in practice to use very small angles of incidence, so that total external reflexion occurs. (The refractive index of matter for x-rays is very slightly less than unity, so that under suitable conditions they exhibit total external reflexion, whereas light exhibits total internal reflexion.) The points B, B', ... thus correspond to the centers of the smooth reflecting portions of the grating. From measurements of the angles of incidence and diffraction under such conditions, the absolute values of the x-ray wavelengths have been derived.

A geometrical representation of Eq. (1) is helpful in extending the theory of diffraction by a grating (an object with a one-dimensional variation of scattering power) to diffraction by a crystal (an object with a three-dimensional variation of scattering power). Equation (1) can be rewritten:

$$\frac{\cos \phi_1}{\lambda} + \frac{\cos \phi_2}{\lambda} = \frac{h}{a} \quad (2)$$

In Fig. 2, OP is a line of length $1/\lambda$ drawn parallel to BA, so that the angle XOP = ϕ_1 , and PQ is a line of the same length drawn parallel to BC, so that it makes an angle ϕ_2 with OX. The projection of OP on OX, OP', is clearly of length $\cos \phi_1/\lambda$, and the projection of PQ, P'Q', is of length

FIG. 2. Geometrical representation of the condition for strong reflection.

$\cos \phi_2/\lambda$. If Eq. (2) is satisfied, the length of $OQ' = OP' + P'Q'$ must be h/a . Clearly, fixing h is not sufficient to fix the angles ϕ_1 and ϕ_2 . If we imagine that the lines XO, OP and PQ are jointed together at O and P, Q is free to slide up and down the line GQ'H within wide limits without affecting the equality of Eq. (2), and so giving considerable freedom to the directions of incident and diffracted rays having a constant path difference $h\lambda$. Different values of h lead to different lines GH, G'H', ... spaced at integral multiples

of the distance $1/a$ along OX. All possible mutual relationships between the incident and strongly diffracted rays are represented by those portions of the set of parallel lines of spacing $1/a$ that lie within a circle with radius $2/\lambda$ and center O.

The exterior angle between AB and BC is generally denoted by 2θ . From Fig. 1 it is clear that

$$2\theta = \phi_2 - \phi_1 \quad (3)$$

and from Fig. 2

$$\begin{aligned} OQ &= OP \sin \theta + PQ \sin \theta \\ &= (2 \sin \theta)/\lambda \end{aligned} \quad (4)$$

With a little reinterpretation, Figs. 1 and 2 can be used to derive the condition for strong diffraction by a crystal. A crystal is a three-dimensionally periodic object, with a certain arrangement of atoms repeating indefinitely at intervals of a in one direction, b in another, and c in a third. The intervals a , b , c are not generally equal to each other, nor necessarily at right angles to each other. They define a parallelepiped called the *unit cell* of the crystal. For determining the geometrical conditions for the existence of a strong diffracted beam, the manner in which the atoms are arranged in the cell is not important, and for the moment we may think of them as forming a single scattering center at the corner of the cell. In Fig. 1, the points B, B', ... now represent a row of scattering centres parallel to a , and ABC, A'B'C', ... represent a sequence of incident and diffracted rays. The difference is that for a ruled grating one can expect constructive interference between the various scattered rays only if OX, AB, BC, A'B', B'C', ... are coplanar, whereas an arrangement of atoms can scatter out of the plane of OX and AB, and hence BC need not lie in this plane. The condition for reinforcement, however, remains

$$D'B' - DB = h\lambda \quad (5)$$

and its geometrical representation in Fig. 2 is changed only in that Q does not necessarily lie in the plane of OX and OP. With this relaxation, the condition for reinforcement is fulfilled if Q lies anywhere on a plane perpendicular to a and distance h/a from O. Different values of h lead to a set of parallel planes, and as far as the repetition of scattering centers in the direction of a is concerned, reinforcement will occur if Q lies anywhere on any of the planes within a sphere with center O and radius $2/\lambda$.

It is, however, necessary to satisfy similar conditions for the repetition of scattering centers in the directions of b and c . These conditions are exactly analogous: reinforcement for repetition along b will occur only if Q lies in one of a set of planes that are perpendicular to b and spaced $1/b$ apart, and reinforcement for repetition along c will occur only if Q lies in one of a set of planes perpendicular to c and spaced $1/c$ apart. There can be a strong beam diffracted by the crystal only if Q satisfies these three conditions

simultaneously. Two sets of planes intersect in a set of parallel lines, and the third set of planes will intersect these lines in a lattice of points. This is called the lattice reciprocal to the crystal lattice, or the *reciprocal lattice* for short. A strong diffracted beam can occur, then, only if Q coincides with one of the points of the reciprocal lattice, and only those points within a sphere of radius $2/\lambda$ are possible, since the maximum length of OQ is $2/\lambda$. This sphere is called the *limiting sphere*.

The repeat distances in the reciprocal lattice are usually called a^* , b^* , c^* . They have the same general directions as a , b , c , but are actually parallel to them only in those crystal systems that have their axes at right angles. There are a number of "reciprocal" relations between the two sets of axes, some obvious from the way in which the reciprocal lattice has been constructed, others obtainable only by analysis. For further details the article on CRYSTALLOGRAPHY should be consulted.

For a given wavelength λ , a given direction of incidence PO, and a fixed position of the crystal, the loci of possible positions of Q is a sphere with center P and radius $1/\lambda$. This sphere is called the *sphere of reflexion*, since strong diffraction can take place only if one of the points of the reciprocal lattice lies in or passes through its surface. With all parameters fixed, this is an unlikely coincidence, and in the practical study of x-ray diffraction, provision must be made for variation of either λ (the Laue method), or the orientation of the crystal (most types of single-crystal and crystal-powder cameras and diffractometers), or the direction of the incident x-rays (some special-purpose techniques). Space does not permit discussion of the practical details.

In the preceding treatment diffraction has been considered from the viewpoint of adding contributions scattered by centers arranged in a regular lattice. It can also be considered as reflexion from sets of parallel planes of atoms, the rays reflected by successive planes in a set being added. It can be shown that the connection between the two views is that (1) the line OQ joining the origin of the reciprocal lattice to the point hkl is perpendicular to the corresponding set of reflecting planes, and (2) its length is the reciprocal of their spacing d . From the second viewpoint, then, Eq. (4) may be rewritten

$$\lambda = 2d \sin \theta \quad (6)$$

a relation known as *Bragg's law*.

The arrangement of atoms within the unit cell influences the intensity of the various orders of diffraction hkl , just as the shape of the ruling influences the intensities of the different orders produced by an optical diffraction grating. It is easy to see that x-rays diffracted by an atom at the position xa , $y b$, $z c$ within the unit cell travel a shorter distance than those diffracted at the hypothetical scattering center at the origin, and that the corresponding phase difference is $2\pi(hx + ky + lz)$. If the cell contains n atoms whose scattering

factors (the ratio of the actual scattered amplitude to the amplitude scattered by a free electron under the same conditions) are f_1, f_2, \dots, f_n , the total amplitude scattered by the cell will thus have an in-phase component of

$$A = f_1 \cos 2\pi(hx_1 + ky_1 + lz_1) + \dots + f_n \cos 2\pi(hx_n + ky_n + lz_n) \quad (7)$$

and an in-quadrature component of

$$B = f_1 \sin 2\pi(hx_1 + ky_1 + lz_1) + \dots + f_n \sin 2\pi(hx_n + ky_n + lz_n) \quad (8)$$

the scattering by an atom at the origin of the cell being taken as the reference phase. The total intensity of scattering is thus proportional to

$$F^2 = A^2 + B^2 \quad (9)$$

The quantity F is called the *structure factor*; it is sometimes convenient to regard it as a complex quantity $F = A + iB$. It can vary in magnitude from zero to $f_1 + f_2 + \dots + f_n$, with a root-mean-square value of $\sqrt{(f_1^2 + \dots + f_n^2)}$. The total intensity of the order hkl is proportional to NF^2 , where N is the number of unit cells in the crystal.

The maximum intensity of diffraction occurs when the point Q , defined above, coincides with one of the points hkl of the reciprocal lattice. As the point Q moves away from its ideal position, the intensity of diffraction does not drop instantaneously to zero, but falls off gradually in a manner depending on the size and perfection of the crystal. The study of the manner in which the falling off occurs is a fascinating exercise both experimentally and theoretically, but space permits only the quotation of a few qualitative results. The main varieties of imperfection considered are (1) the crystal is too small to give sharp diffraction maxima, (2) there are "mistakes" in the arrangement of atoms in the sequence of unit cells, and (3) the crystal is twisted, bent, or affected by dislocations. In case (1) the regions round each reciprocal-lattice point are identical except for variations in F , and extend in any direction to a distance that is roughly the reciprocal of the thickness of the crystal in the corresponding direction. In case (2) the size and shape of the regions may vary in a complex manner with hkl , but they show no general increase in size with increasing distance from the origin of reciprocal space. In case (3) the size of the regions shows a general increase in direct proportion to their distance from the origin of reciprocal space, as well as varying with hkl .

X-RAYS

Although x-ray (or Roentgen ray) science was 70 years old on November 8, 1965, it maintains a youthful vigor and an ever-accelerating pace in new developments unsurpassed in all other areas of pure and applied science—physical, chemical, biological, medical, industrial or engineering. On that date in 1895, at the University of Wurzburg, Wilhelm Conrad Röntgen observed the fluorescence of a barium platinoeyanide screen, excited by the emission from a Crookes cathode-ray tube of a "new kind of ray", penetrating through space invisible, unaffected by electric or magnetic fields, differentially absorbed in passing through matter of varying composition, density or thickness, ionizing gases and affecting electrical properties of liquids and solids, affecting the photographic plate, and producing other chemical and biological reactions. The obvious similarities with light led to the crucial tests of established wave optics: polarization, diffraction, reflection and refraction. With limited experimental facilities, Röntgen and his contemporaries could find no evidence of any of these, hence the designation x (unknown) of x-rays generated by the stoppage at anode targets of cathode rays, identified by J. J. Thomson in 1897 as electrons, accelerated by a potential of a few thousand volts in evacuated tubes.

In 1906 Barkla found evidence in scattering experiments that x-rays could be polarized or constrained to vibrate in one direction perpendicular to the direction of beam propagation. The really convincing proof of the nature of x-rays, placing them in the long range of electromagnetic waves with visible, ultraviolet and infrared light, radio and Hertzian waves, and eventually with gamma rays from radioactive sources, was the discovery of diffraction of collimated beams by crystals acting as three-dimensional gratings (simultaneously proving the regularity of crystalline architecture). The beautiful diffraction pattern of a zinc sulfide crystal photographed in 1912 by von Laue and associates was interpreted soon thereafter by the simple Bragg law: $n\lambda = 2d \sin \theta$ where n is an integer—the order of diffraction, λ is the wavelength of the x-ray beam, d is the interplanar grating spacing of a crystal, and θ is the

angle of incidence (2θ is the angle of diffraction). Thus was founded the science of x-ray spectrometry (λ unknown, d known) and of x-ray diffractometry or crystallography (λ known, d unknown), the experimental measurement in both cases being the angle θ or 2θ .

In 1921 Compton and associates proved that x-rays are reflected from mirrors at small grazing angles of incidence, and are refracted very slightly in the opposite direction from light, and thereby diffracted by ruled gratings. Thus the wave properties of x-rays were finally convincingly demonstrated, but at the same time, the dual nature of the radiation as both waves and corpuscles or photons or quanta became clearly evident. The latter certainly were involved in the photoelectric effect: (1) by the short wavelength limit of the general radiation spectrum sharply defined and represented by $Ve = hc/\lambda_0$ (law of Duane and Hunt, 1915), where V is the voltage applied to the x-ray tube, e is the electronic charge, h is the Planck action constant for quanta, and c is the velocity of light, and (2) by the COMPTON EFFECT, 1922, or an increase in wavelength of scattered radiation as a function of angle, the lost energy appearing as electron recoil.

From 1895 to 1912, the nature of x-rays remained mysterious since there was no method of dispersing the radiation from the target of a tube into a spectrum such as characterized beams of light after refraction in prisms or diffraction by ruled gratings. However, absorption measurements indicated important variations in "quality" — "hard" and "soft" rays — depending upon the target element and the voltage, and the distribution of emitted energy in groups for which Barkla in 1905 devised the nomenclature K, L, M, N, O, P series, by analogy with optical spectral series. The way was opened for the design of the Bragg crystal spectrometer with the discovery of crystal diffraction and the derivation of the Bragg law. With the spectrometer, whose principles still prevail in the automatic high-precision instruments of today, x-ray beams were resolved into spectra of sharp lines in series superposed on a continuous background (the continuous, general or "white" radiation), whose wavelengths were characteristic for each

element. There were also characteristic absorption discontinuities in spectra. Thus Bragg, Moseley, Siegbahn and others began the accumulation of the lists of characteristic wavelengths. Moseley was the first to recognize the essential similarity and simplicity of the K-series, for example, with the same 4 principal lines with wavelengths for each which varied continuously step by step in proceeding from one atomic species to the next in the periodic table. In the immediate intensive effort to account for the origin of x-ray spectra in terms of atomic structure, it was clear that the atomic number [now 1 (hydrogen) to 103 (lawrencium)] is the number of external electrons or the net positive charge on the nucleus of the atom. In this way, the theories of atomic structure arose. First there was the Bohr theory in 1914 of miniature solar systems involving revolutionary concepts introducing the quantum theory of Planck and Einstein. Then followed the gradual change from the mechanical model to the present vector or quantum mechanical model which can only be described mathematically, but with virtually no change in the interpretation of x-ray spectra. The tables of readily available wavelengths are measures of the energies of orbitals in the outer electronic shells of atoms around the nuclei. The original uses of the spectrometer for these physical aspects are fairly well complete and have given way principally to chemical analysis. Spectrometry is only one of at least 25 branches of this radiation science, depending upon techniques, information provided, and modern applications. The attempt is made here for the first time to present a condensed tabulation of these 25 methods (see Table 1). Details in all cases may be found by reference to the companion volume of this Encyclopedia—"The Encyclopedia of X-Rays and Gamma rays," edited by the writer and published by Reinhold Publishing Corp. in 1963.

TABLE I

Method	Instrumental Technique	Information and Uses	Recent Advances
(1) Emission spectrometry	Crystal spectrometer analysis of fluorescent characteristic rays generated in specimen by primary x-rays; photographic film; Geiger, proportional or scintillation counters	Qualitative and quantitative chemical analysis for elements above Cr(6)	1. Automatic, programmed apparatus with discrimination and pulse height analysis. 2. Trace analysis especially in petroleum. 3. Non-dispersive (no crystal) spectrometry greatly extended. 4. Multiple automatic analysis of up to 24 elements. 5. On-stream control of processes (Mg in cement, etc.). 6. Quantitative theory and practice of corrections for matrix effects. 7. Extensions to very long wave-lengths—carbon, 45Å, boron 67Å (Henke)

Method	Instrumental Technique	Information and Uses	Recent Advances
(2) Electron probe microanalyzer	Electron beam collimated by magnetic lenses generates primary rays from areas of $1\mu^2$ (vol $1\mu^3$), analyzed by sensitive spectrometer	Analysis of very small areas or single grains for diffusion, segregation, microscopic processes in alloys, minerals, etc.	1. Several commercial instruments up to \$100 000 on market. 2. Scanning of specimen by electron beam with 1 crystal setting to show distribution of each element as magnified image 3. Accelerating value in biology and medicine. 4. Amazing success in detecting cause of failure in electronic components for guidance systems, semiconductors, etc.
(3) Absorption edge spectrometry	Crystal spectrometer analysis of characteristic absorption by elements in screen from continuous primary spectrum (1K, 3L, 5M edges)	As in (1); long considered relatively insensitive, independent of state or valence of elements	1. Greatly sensitized, automatic apparatus to measure edge height, free from interferences in emission spectra. 2. Highly successful at Oak Ridge for U, Th, Zr, Nb, Mo, Hf, W in presence of variety of matrix elements
(4) Fine Structure of absorption edge	High-resolution spectrometer used as in (3)	K-edge found to have a fine structure dependent on valence of absorbing element	Spectacular success in determining valence state of elements in catalysts such as NaMnO ₂ , on silica unchanged Mn ²⁺ , on charcoal Mn ¹⁺ (Herbstein, South Africa)
(5) Scattering	Fluorescence spectrometer as in (1); sample gas, liquid, solution or solid	In addition to emission lines coherent scattered rays (WLa ₁ from W-target) and incoherent (Compton) rays at larger angle; former detects high atomic number elements in low atomic number matrix	Ratio of intensities, coherent/incoherent, powerful analysis for carbon and hydrogen in organic compounds calibrated with known hydrocarbons and corrections for other elements, more rapid, simpler, equally dependable compared with micro-combustions
(6) Low-angle (Gunnier) scattering	Monochromatic beam falling on certain colloidal samples scattered at very small angles from direct beam (distinguished from small-angle diffraction), as measure of electron density inhomogeneity	Colloids or heterogeneous systems of clumps, holes, voids, pores with discontinuity from 10 to 10 000 Å, measured for radius of gyration, <i>R</i> , related to particle size	1. Until recently purely academic but now widely used with proteins, viruses, catalysts, carbon blacks, hardening and precipitation in alloys, lattice deformations. 2. Invaluable for study of critical phenomena (liquid-vapor) 3. Best method for voids in fibers, vitreous silicates, etc
(7) Absorptometry	Measurement of attenuation of x-ray beam passing through matter with intensity before and after; polychromatic and monochromatic beams	Chemical analysis of gases, liquids, solutions, solids, with proper calibration; true densities, porosities; coating, plating, insulation thickness	1. Automatic double-beam photometers with chopper, and multiplier phototubes with vastly improved phosphors and intensification, often linked with servomechanisms. 2. Automatic gauging on-stream in metal rolling mills 3. Automatic densitometry of static and fluid beds, and porosity of coke etc. 4. <i>In vivo</i> measurement of bone density, iodine in thyroid (dichromatic)
(8) Radiography	Registration on film of differential absorption of beam passing through specimen of varying composition density ("shadow-graphs")	Medical diagnosis; industrial testing of internal soundness (castings, forgings), correct fabrication, etc.	1. Manifold increase in nondestructive testing in art museums, especially paintings for authenticity, repair, hidden images. 2. Wide advance of supervoltage radiography of thick sections (betatrons, Van de Graaff and linear accelerators.) 3. New use of color film, polaroid 10-second developing film, Xerox images, and far more frequent enlargement of images
(9) Flash and cineradiography	Instantaneous and motion picture sequences with extremely intense beams	Recording of events radiographically in times as short as 1 nsec (10^{-9} sec)	1. Field emission (sharp-pointed cold cathode) tubes with currents of hundreds of amperes in pulses and intensities in millions of roentgens. 2. Used in ballistics, explosions. 3. Biological use illustrated by experiments on small animals strapped in car shot from bow at 30G acceleration, showing amazing displacement of internal organs (significant for human astronauts)

Method	Instrumental Technique	Information and Uses	Recent Advances
(10) Fluoroscopy	Shadows of gross structures registered on fluorescent screen	Medical observation of internal motions and course of surgery; motions of machinery. Always handicapped by weak intensity and exposure danger to patients; shoe-fitting prohibited in many states by law	1. Technique revolutionized by electronic intensifiers in use of very weak primary rays free from exposure danger. 2. Growing use of radioisotope x-ray sources hitherto far too weak, for mobility in field, simplicity, high penetration of high-energy rays
(11) Tomoscopy	X-ray source and intensifier on each side of object, projecting image on fluorescent screen, moved synchronously, parallel and in opposite directions	Produces image of a single plane in interior of object; serioscopy a series of planar images through object by readjustment	Entirely new because of efficient intensifiers, to localize exactly any feature obscured by 3 dimensions superposed in usual fluoroscopic image
(12) Contact microradiography	Beam of monochromatic or very soft x-rays pass through small specimen in contact with photographic emulsion, and image enlarged, usually 100 \times , with interference from graininess	One type of x-ray microscopy known for 50 years but used only recently, useful for any kind of specimen with heterogeneous absorbing power	1. New fine-grained emulsions permitting higher magnifications up to 800 \times . 2. Grainless media such as polymer sheets cross-linked by exposure to change solubility and form relief of image shadow-cast and examined by electron microscope. 3. Single-cell images by use of very soft rays such as C-K α at 45Å (Henke) 4. Microangiography (blood vessels with opaque stains) developed at Mayo Clinic as accepted diagnostic method 5. Stereomicroradiography with ingenious apparatus for 3-dimensional view.
(13) Microfluoroscopy	Absorption image on fluorescent screen microscopically examined and photographed	Useful for observation of changes or even cellular motion at higher magnifications than with film from much smaller grain size than silver halides in film	Entirely new technique by Pattee (Stanford)
(14) Projection microscopy	X-rays from point source generated by electrons collimated by magnetic lenses registered as sharp images on film or screen at various distances with inherent enlargement without penumbra or limitation of graininess	Same as (12) and (13) but much more direct, rapid and higher magnifications	Removes all interference from graininess of film since enlarged image formed directly; dramatic micrographs of freeze-dried biological specimens now being published
(15) Reflection microscopy and telescropy	Original Kirkpatrick microscope with true optics of total reflection of x-rays from cylindrical or elliptical lenses in multiple	Theory and practice at stage of rapid development for microscope and for telescopic enlargement of solar and celestial x-rays	See column at left
(16) Radiation chemistry, radiolysis	Irradiation of all types of materials from intense source and evaluation of chemical change from absorbed dose in rads (100 ergs/g)	Radiation-induced chemical reactions by formation of intermediate excited species, ions, free radicals; thus many dosimeters and potential radiation processes, and aid in accounting for biological effects	1. Immeasurably great recent progress in mechanisms and in manufacturing - ethyl bromide (Dow), phenol from benzene and water (Russia), cross-linking of polyethylene, etc., for insulation, removal of mercaptans from petroleum, graft polymerization, rubber vulcanization, synthesis of organic compounds with CO ₂ , producing NF ₃ oxidizer for rocket fuels. 2. Discovery of hydrated electron as essential intermediate in aqueous systems by E. J. Hart. 3. Acceptance of G (M. Burton) for reporting yields; number of molecules reacting or produced per 100 eV absorbed radiation energy

Method	Instrumental Technique	Information and Uses	Recent Advances
(17) Radiation physics	Same as (16)	Directed to study of "damage" in solids by excitation and ionization of electrons, atomic displacements or defects in lattices with effects on mechanical, thermal, electrical, magnetic, optical, color properties	1. Now an essential tool of solid-state physics, in research and production of semiconductors-transistors, rectifiers, diodes, infrared detectors, solar batteries. 2 Just announced in advertisements irradiation of LiF crystals to permit cleavage for use in many instruments.
(18) Radiation biology	Same as (16) and (17) on living systems	Effects of radiation exposure on all organisms, especially sterilization, potato sprout inhibition, intensive research since "fallout" on chemical, physical and biological changes in cell constituents on up to whole body	1. Food preservation without refrigeration by bacterial sterilization, a major project of the Army and AEC. Bacon approved in 1963 by FDA to be followed by meats, chicken, fish, fruits, vegetables. 2. Soybean seeds surviving a million roentgen x-ray dose with improved yields, unexpectedly due to lethal effect on 4 million bacteria per seed with release of pyrogenic protectant of plant cells
(19) Radiation genetics	Same as (18) with special concern with reproductive cells	To produce and study mutations some it is hoped useful, by effects on DNA, chromosomes and genes	1. More than ever before a search for favorable mutations in crop plants, flowers, etc. 2. Intensive research related to cancer cells, nature of DNA (deoxyribonucleic acid) and RNA (ribonucleic acid) in terms of variations in amino acid sequences
(20) Radiation therapy	Irradiation of cancer and other neoplasms in controlled doses, massive and fractional	Slow, step-by-step, upward climb with mounting hopes, with best results from supervoltage (1-12 MeV) rays	Increasing use of isotopic sources of x-rays, as well as γ -rays, and skillful combination with new chemotherapeutic agents, surgery and transplantations
(21) Radiation protection	Special case of (16) in test of chemicals as protective agents against x-rays in chemical and biological systems,	Preferential absorption or energy, destruction of free radicals or other intermediates from ionizing rays, by wide range of compounds	Among thousands of compounds tested, sulfur-containing cysteine, cysteamine and ALI (ammonioethylisothiuronium bromide hydrobromide, now on market in tablet form) most extensively studied and among most effective in protecting living organisms against deleterious radiation effects when inbibed before exposure, toxicity of drugs serious factor and shielding from radiation still surest protection
(22) Single-crystal analysis	Diffraction of x-rays by crystals discovered by von Laue in 1912, Laue stationary film and sample, rotating crystal, and moving-film methods for patterns	Ultimate crystal and molecular structures of increasingly complex compounds, derived from patterns, penicillin analysed to synthesis; control of cutting of quartz crystals for electronics, and identification of gems among industrial uses	1. Vast improvements in automatic apparatus and intensity measurements, in mathematical theory and interpretation such as Fourier, Patterson, Hosemann functions, fold integrals, ingenious handling of inherent phase problem, in aids such as computers, optical analog devices and summators, reciprocal lattice concept, molecular transforms, stochastic methods. 2. Successful analysis of many complex biologically important compounds such as all types of fibrous proteins. 3. Quantitative detection and evaluation of thermal oscillations producing anomalous interferences, coefficients of expansion, mosaic structure and imperfections in single crystal
(23) Powder diffraction analysis	Patterns of random powders and aggregates in many kinds of cameras yielding line patterns, each a "fingerprint" of a given element or compound, many listed in ASTM card index	Identification of crystalline material, quantitative analysis of mixtures, solid solutions, reactions, etc.; one of the most widely used instrumental methods of analysis	1. Automatic recording programmed diffractometers of great value in time saving, accuracy and interpretation. 2. New microcameras and complete apparatus for patterns at low and high temperatures and pressures, essential in phase studies. 3. Exceptional advance in precision measurements of lattice parameters indicative of lattice perfection, atomic weights, ideal densities, polymorphic equilibria, etc. (Straumanis, Beu <i>et al.</i>). 4. Radial distribution analysis of amorphous materials

Method	Instrumental Technique	Information and Uses	Recent Advances
(24) Texture analysis	Diffraction patterns by usual techniques of (23) plus special apparatus such as pole-figure goniometers, back-reflection, etc.	Determination whether crystalline or amorphous, per cent of each, preferred orientation, grain sizes in microscopic and colloidal ranges, strains and defects.	The essence of solid-state science and the area of greatest progress in theory and practice in study of materials in terms of behavior, beyond actual lattice structure, and changes due to environmental effects; covered in massive new treatise published by Springer, Germany
(25) Topography	Special textural analysis, technique due to Lang (Bristol) usually with specimen and film traversed back and forth together in x-ray beam	Since strained and imperfect crystal area diffract more strongly than perfect, dislocations beautifully detected and identified topographically	One of the great new techniques of utmost practical value in disclosing how and why materials fail, how crystals grow, what physical and mechanical measurements of tensile strength and deformation mean.

Z

ZEEMAN AND STARK EFFECTS*

In 1896 Zeeman observed that the yellow lines of a sodium flame were considerably broadened when it was placed in a strong magnetic field. Using his electron theory of matter and radiation, Lorentz showed that the light should be circularly polarized when viewed along the field (σ components), and linearly polarized along (π components) and perpendicular to the field direction (σ components), when viewed transverse to the magnetic field. This was verified by Zeeman using a Nicol prism to analyze the polarization.

A magnetic field exerts a force $-e/c[\mathbf{v} \times \mathbf{H}]$ on an electron with a velocity \mathbf{v} . Hence, a field H_z does not affect motion in the z direction, but electrons moving in counterclockwise directions in the $x-y$ plane are speeded up by the magnetic field, while those moving in a clockwise direction are slowed down giving frequency changes

$$\Delta\nu = \pm eH/4\pi m_e c = 1.4H \times 10^6 \text{cps}$$

(e is the electronic charge in electrostatic units, H is the magnetic field in oersteds, m_e is the mass of the electron and c is the velocity of light). Expressed in wave numbers

$$\Delta\tilde{\nu} = eH/4\pi m_e c^2 = 4.6688 \times 10^{-5} H \text{cm}^{-1}$$

which is called a Lorentz unit. Figure 1 shows the normal Zeeman effect, or Lorentz triplet, obtained with this theory. Such triplets were soon observed in cadmium and zinc by Preston, and provided clear indication that the emission of light by atoms involved the motion of negatively charged electrons. Most Zeeman patterns are anomalous, however, and show more than three components (see Fig. 1). Such complex patterns require a quantum mechanical interpretation, including the concept of electron spin. They depend only on the angular momentum quantum numbers of the terms in the spectral series (Preston's rule), and all known patterns are rational multiples of the normal triplet separation (Runge's rule).

According to quantum theory, the angular momentum, $P_l = \hbar/2\pi$, of the electron is quantized and is represented by a vector \mathbf{l} normal to the orbit. The magnetic moment of the electron is then $\mu_l = -le/2m_e c$. Magnetic field effects are then equivalent to a precession of \mathbf{l} around \mathbf{H} at

FIG. 1. Zeeman effect on spectral line: (a) No magnetic field—unshifted line. (b) Normal Zeeman effect. Transverse magnetic field, π and σ components of normal Lorentz triplet. (c) Normal Zeeman effect viewed along magnetic field. Circularly polarized σ components. (d) Anomalous Zeeman effect of the transition $2d_{5/2}-2P_{3/2}$.

the Larmor frequency $\nu_L = eH/4\pi m_e c$. Only discrete angles between \mathbf{l} and \mathbf{H} are allowed given by the projection m of \mathbf{l} on \mathbf{H} , where m takes values $-l$ to $+l$. The energy splitting of the l term is thus $m\hbar eH/4\pi m_e c$, and the selection rules $\Delta m = 0, \pm 1$ apply for allowed transitions between different l terms. Corresponding frequency shifts are 0 and $\pm eH/4\pi m_e c$, which again gives the normal Zeeman effect. Landé used such vector models and introduced empirically the g_l factor for each l term, with energy separations $\Delta E_l = m\hbar g_l eH/4\pi m_e c$. He was able to deduce the appropriate g_l factors and explain the Zeeman patterns to a remarkable degree.

The spin of the electron, postulated by Uhlenbeck and Goudsmit, allowed a more satisfactory deduction of these g factors. To account for the doublet fine structure in the alkali metals, e.g., the D-lines of sodium, a spin s of $\frac{1}{2} \frac{\hbar}{2\pi}$, and a magnetic moment $\mu_s = -s 2e/2m_e c$, were ascribed to the electron as inherent properties, and a total angular momentum quantum number $j = l + s$ for a single valence electron. The resulting vector

* Sponsored by Lockheed Independent Research Program.

model of the atom is shown in Fig. 2. The magnetic interaction between the angular and spin momenta of the electron results in a coupling between l and s which then precess rapidly about their resultant j . In weak magnetic fields, j precesses slowly about H_z at the Larmor frequency times the g factor. From this vector model, we obtain

$$g = \frac{j(j+1) + s(s+1) - l(l+1)}{2j(j+1)}$$

where, in accordance with observation and the more accurate quantum mechanical deduction, j^2 , l^2 , and s^2 are replaced by $j(j+1)$, $l(l+1)$, and $s(s+1)$ respectively.

FIG. 2. Vector model of angular momenta l , s , j , and projection m of j along H for a single valence electron. Classical precession of j around H .

The magnetic quantum number m takes values j through $-j$; transitions $\Delta m = 0$ correspond to π components, $\Delta m = \pm 1$ to σ components. Selection rules $\Delta j = 0, \pm 1$ ($j = 0$ to $j = 0$ excluded) are also effective. For the transition $^2S_{1/2} \rightarrow ^2P_{3/2}$, or the D_2 -line of sodium, $l = 0$, $s = 1/2$, $j = 1/2$, $g = 2$; and $l = 1$, $s = 1/2$, $j = 3/2$, $g = 4/3$ for the lower and upper levels respectively. In terms of the normal Zeeman separation, namely, $eH/4\pi mc$, the mg values for the upper and lower levels are

$$\begin{array}{ccccccc} m & & -3/2 & -1/2 & 1/2 & 3/2 \\ mg_{\text{upper}} & \rightsquigarrow & -2 & -2/3 & 2/3 & 2 \\ mg_{\text{lower}} & \rightsquigarrow & -1 & -1/3 & 1/3 & 1 \end{array}$$

where the arrows indicate possible transitions $\Delta m = 0, \pm 1$, and give the positions of all Zeeman lines as differences between the mg terms of the two levels. These differences are $\pm 5/3$, ± 1 , $\pm(1/3)$ and give a Zeeman pattern of 6 lines for the D_2 -line of sodium (π transitions are in parentheses). Figure 3 shows the splitting and the intensities of the various transitions which depend

on the quantum numbers j and m . Anomalous Zeeman effects for other transitions and atoms are dealt with similarly. For atoms with more than one valence electron, appropriate coupling schemes between the angular and spin momenta of the electrons, such as Russell-Saunders L - S coupling, must be used in an analogous way.

FIG. 3. Transitions involved in the anomalous Zeeman effect of the 5890 Å D_2 -line of sodium ($^2S_{1/2} \rightarrow ^2P_{3/2}$). Intensities of the π and σ components also shown.

For very strong magnetic fields, the precession frequency of j around H becomes comparable with that of l and s around j , or with the fine structure separation. This is the Paschen-Back effect region, where the fine structure coupling breaks down; l and s then precess independently around H , and the normal Zeeman pattern is observed. Paschen-Back effects have been observed in lighter elements such as Li, where the doublet separation of the 2P levels is only 0.34 cm^{-1} as compared with 17.2 cm^{-1} for the D-lines of sodium. Since 10 000 oersteds corresponds to a Larmor splitting of 0.47 cm^{-1} , very high magnetic fields are necessary with heavier atoms. In the intermediate region of magnetic fields, more elaborate quantum mechanical methods are necessary; however, a magnetic field is only strong or weak in a relative sense as compared with other internal fields in the atom.

Hyperfine structure of spectral lines involves the nuclear spin I , and a magnetic field which is weak for fine structure may be quite strong for hyperfine structure. Here the quantum number $F = I + J$ is used to determine the magnetic splitting. In optical spectra, such weak-field magnetic splittings are rarely observed because the hyperfine structure splitting is comparable with the Doppler width of the line or the instrumental resolution. Hyperfine splittings of the ground state are used in atomic beam resonance techniques to determine I , and also in atomic beam frequency standards. At higher values of magnetic field, the coupling between I and J breaks down and I and J precess independently

around H giving the Back-Goudsmit effect in hyperfine structure.

Zeeman spectra of many atoms have been observed with magnetic fields of 20 000 to 40 000 oersteds and diffraction gratings capable of resolving 1/10 of a Lorentz unit. Completely resolved spectra give the g factors and the j values of both levels involved in the transition, and the Zeeman effect has played a dominant role in the elucidation of atomic spectra.

In 1913 Stark demonstrated that every spectral line of the Balmer series of hydrogen was split into a number of components when the emitting atoms, obtained from the positive rays in a hydrogen discharge, were subjected to electric fields of 100 000 volts/cm. Lo Surdo obtained similar results using the large potential gradient in the dark space of a glow discharge. This symmetrical splitting of the hydrogen lines is due to a linear Stark effect, with a shift of the atomic levels in wave numbers given by

$$T = AF + am_m$$

Here $A = 6.45 \times 10^{-5} n(n_2 - n_1)$; F is the electric field in volts per centimeter; a is a constant; m_l and m_s are the projections of orbital and spin angular momentum on the field direction (cf. the magnetic quantum number m); n is the principal quantum number, and n_1, n_2 are other quantum numbers deduced from the Bohr quantum theory which successfully explained the effect. Certain components of the Stark pattern occur only in transverse observation and are polarized with the electric vector parallel to the field (π components). Others are polarized perpendicular to the field (σ components). For observations along the field, only the σ components appear, and these are unpolarized.

Such a linear Stark effect occurs only in hydrogen, or hydrogen-like atoms, and is due to the close proximity of levels with the same n but different angular momenta l . The quantum number m_l is analogous to the magnetic quantum number m , but with the important difference that values $\pm m_l$ now give identical splittings of energy levels. This occurs since the energy depends only on the orientation of the orbit to the electric field and not on the sense of precession as in a magnetic field. The unpolarized nature of the σ components when observed along the electric field is also due to this independence of energy on the sign of m_l .

For fields greater than 100 000 volts/cm hydrogen exhibits a quadratic Stark effect, with a shift of all spectral lines towards the red or violet.

A similar quadratic Stark effect is observed in all other atoms, where the fields are now weak compared with the separation of states of different parity, or l values. For the sodium D-lines, transitions $3s^2S_{1/2} - 3p^2P_{1/2, 3/2}$, the states arising from different electron orbits, or l values, with the same quantum number n are widely separated. These were studied by Ladenburg at fields of 160 000 volts/cm, when only a quadratic Stark effect was observed. The various components of the D-lines, which split into levels with $m_l = \pm 1/2$, and $m_j = \pm 1/2, \pm 3/2$ respectively, were shifted towards the red by a fraction of an angstrom unit. Similar results were obtained for other alkali metals. The effect increases rapidly with the total quantum number n and may be observed in absorption as well as emission. Forbidden transitions, violating the selection rule $\Delta l = \pm 1$, also occur due to a mixing of the energy levels in strong electric fields. These have been observed, particularly in helium by Foster who used electric fields up to 85 000 volts/cm.

The Stark effect is closely connected with the polarizability of the otherwise neutral atom. The various orientations of the angular momentum l then correspond to states of slightly different energies and produce the observed quadratic Stark effect. Because of its complex nature, the Stark effect, in comparison with the Zeeman effect, has not played a dominant role in the analysis of complex spectra or of atomic structure.
